IWLA currently sponsors several environmental programs designed to conserve **natural resources** and educate the public. The aforementioned Save Our Streams (SOS) program is a grassroots organization designed to monitor **water quality** in streams and rivers. Through 200 chapters nationwide, SOS promotes "stream rehabilitation" through stream adoption kits and water pollution law training. Another program, **Wetlands** Watch, allows local groups to purchase, adopt, and protect nearby wetlands. Similarly, the Izaak Walton League Endowment buys land to save it from unwanted development. IWLA's Uncle Ike Youth Education program aims to educate children and convince them of the necessity of preserving the **environment**. A last major program from the League is its internationally acclaimed Outdoor Ethics program. Outdoor Ethics works to stop **poaching** and other illegal and unsportsmanlike outdoor activities by educating hunters, anglers, and others.

The League also sponsors and operates regional conservation efforts. Its Midwest Office, based in Minnesota, concentrates on preservation of the Upper Mississippi River region. The **Chesapeake Bay** Program is a major regional focus. Almost 25% of the "Ikes" live in the region of this **estuary**, and public education, awards, and local conservation projects help protect Chesapeake Bay. In addition the **Soil Conservation** Program focuses on combating soil erosion and **groundwater pollution**, and the Public Lands Restoration Task Force works out of its headquarters in Portland, Oregon, to strike a balance between forests and the desire for their natural resources in the West.

IWLA makes its causes known through a variety of publications. *Splash*, a product of SOS, enlightens the public as to how to protect streams in America. *Outdoor Ethics*, a newsletter from the program of the same name, educates recreationists to responsible practices of **hunting**, boating, and other outdoor activities. The League also publishes a membership magazine, *Outdoor America*, and the *League Leader*, a vehicle of information for IWLA's 2,000 chapter and division officers. IWLA has also produced the longest-running weekly environmental program on television. Entitled *Make Peace with Nature*, the program has aired on PBS for almost 20 years and presents stories of environmental interest.

Having expanded its scope from water to the general environment, IWLA has become a vital force in the national conservation movement. Through its many and varied programs, the League continues to promote constructive and active involvement in environmental problems.

J

Wes Jackson (1936 –)

American environmentalist and writer

Wes Jackson is a plant geneticist, writer, and co-founder, with his wife Dana Jackson, of the **Land Institute** in Salina, Kansas. He is one of the leading critics of conventional agricultural practices, which in his view are depleting **topsoil**, reducing genetic diversity, and destroying small family farms and rural communities. Jackson is also critical of the culture that provides the pretext and the context within which this destruction occurs and is justified as "necessary," "efficient," and "economical." He contrasts a culture or mind-set that emphasizes humanity's mastery or dominion over **nature** with an alternative vision that takes "nature as the measure" of human activity. The former viewpoint can produce temporary triumphs but not long-lasting or sustainable livelihood; only the latter holds out the hope that humans can live with nature, on nature's terms.

Jackson was born in 1936 in Topeka, Kansas, the son of a farmer. Young and restless, Jackson held various jobs—welder, farm hand, ranch hand, teacher—before devoting his time to the study of agricultural practices in the United States and abroad. He attended Kansas Wesleyan University, the University of Kansas, and North Carolina State University, where he earned his doctorate in plant genetics in 1967.

According to Jackson, agriculture as we know it is unnatural, artificial, and, by geological time-scales, of relatively recent origin. It requires plowing, which leads to loss of topsoil, which in turn reduces and finally destroys fertility. Large-scale "industrial" agriculture also requires large investments, complex and expensive machinery, fertilizers, pesticides, and herbicides, and leads to a loss of genetic diversity, to **soil erosion** and **compaction**, and other negative consequences. It is also predicated on the planting and harvesting of annual crops—corn, wheat, soybeans—that leaves fields uncovered for long periods and thus leaves precious topsoil unprotected and vulnerable to erosion by wind and water. For every bushel of corn harvested, a bushel of topsoil is lost. Jackson estimates that America has lost between one-third and one-half of its topsoil since the arrival of the first European settlers.

At the Land Institute, Jackson and his associates are attempting to re-think and revise agricultural practices so as to "make nature the measure" and enable farmers to "meet the expectations of the land," rather than the other way around. In particular, they are returning to, and attempting to learn from, the native **prairie** plants and the ecosystems that sustain them. They are also exploring the feasibility of alternative farming methods that might minimize or even eliminate entirely the planting and harvesting of annual crops, favoring instead the use of perennials that protect and bind topsoil.

Jackson's emphasis is not exclusively scientific or technical. Like his long-time friend Wendell Berry, Jackson emphasizes the *culture* in agriculture. Why humans grow food is not at all mysterious or problematic: we must eat in order to live. But how we choose to plant, grow, harvest, distribute, and consume food is clearly a cultural and moral matter having to do with our attitudes and beliefs. Our contemporary consumer culture is out of kilter, Jackson contends, in various ways. For one, the economic emphasis on minimizing costs and maximizing yields ignores longer-term environmental costs that come with the depletion of topsoil, the diminution of genetic diversity, and the depopulation of rural communities. For another, most Americans have lost (and many have never had) a sense of connectedness with the land and the natural **environment**; Jackson contends that they are unaware of the mysteries and wonder of birth, death and rebirth, and of cycles and seasons, that are mainstays of a meaningful human life. To restore this sense of mystery and meaning requires what Jackson calls *homecoming* and "the resettlement of America," and "becoming native to this place." More Americans need to return to the land, to repopulate rural communities, and to re-learn the wealth of skills that we have lost or forgotten or never acquired. Such skills are more than matters of method or technique, they also have to do with ways of relating to nature and to each other. Jackson has received several awards, such as the Pew

Conservation Scholars award (1990) and a MacArthur Fellowship (1992).

Wes Jackson has been called, by critics and admirers alike, a radical and a visionary. Both labels appear to apply. For Jackson's vision is indeed radical, in the original sense of the term (from the Latin *radix*, or root). It is a vision not only of "new roots for agriculture" but of new and deeper roots for human relationships and communities that, like protected prairie topsoil, will not easily erode.

James Bay hydropower project

James Bay forms the southern tip of the much larger Hudson Bay in Quebec, Canada. To the east lies the Quebec-Labrador peninsula, an undeveloped area with vast expanses of pristine **wilderness**. The region is similar to Siberia, covered in **tundra** and sparse forests of black spruce and other evergreens. It is home to roughly 100 **species** of birds, twenty species of fish and dozens of mammals, including muskrat, lynx, black bear, red fox, and the world's largest herd of caribou. The area has also been home to the Cree and other Native Indian tribes for centuries. Seven rivers drain the wet, rocky region, the largest being the La Grande.

In the 1970s, the government-owned Hydro-Quebec electric utility began to divert these rivers, **flooding** 3,861 square miles (10,000 km^2) of land. They built a series of reservoirs, **dams** and dikes on La Grande that generated 10,300 megawatts of power for homes and businesses in Quebec, New York, and New England. With its $16 billion price tag, the project is one of the world's largest energy projects. The complex generates a total of 15,000 megawatts. A second phase of the project added two more hydroelectric complexes, supplying another 12,000 megawatts of power--the equivalent of more than thirty-five nuclear **power plants**.

But the project has had many opponents. The Cree and other Inuit tribes joined forces with American environmentalists to protest the project. Its environmental impact has had scant analysis; in fact, damage has been severe. Ten thousand caribou drowned in 1984, while crossing one of the newly-dammed rivers on their **migration** route. When the utility flooded land, it destroyed **habitat** for countless plants and animals. The graves of Cree Indians, who for millennia, had hunted, traveled, and lived along the rivers, were inundated. The project also altered the **ecology** of the James and Hudson bays, disrupting spawning cycles, **nutrient** systems, and other important maritime resources. Naturally-occurring **mercury** in rocks and **soil** is released as the land is flooded and accumulates as it passes through the food chain from microscopic organisms, to fish, to humans. A majority of the native people in villages where fish are a main part of the diet show symptoms of mercury **poisoning**.

Despite these problems, Hydro-Quebec pursued the project, partly because of Quebec's long-standing struggle for independence from Canada. The power is sold to corporate customers, providing income for the province and attracting industry to Quebec.

The Cree and environmentalists, joined by New York congressmen, took their fight to court. On **Earth Day** 1993, they filed suit against New York Power Authority in United States District Court in New York, challenging the legality of the agreement, which was to go into effect in 1999. Their claim was based on the United States Constitution and the 1916 Migratory Bird Treaty with Canada.

In February 2002, nearly 70 percent of Quebec's James Bay Cree Indians endorsed a 2.25 billion dollar deal with the Quebec government for hydropower development on their land. Approval for the deal ranged from a low of 50 percent, to a high of 83 percent, among the nine communities involved. Some Cree spokespersons considered the agreement a vindication of the long campaign, waged since 1975, to have Cree rights respected.

Under the deal, the James Bay Cree would receive $16 million in 2002, $30.7 million in 2003, then $46.5 million a year for 48 years. In return, the Cree would drop environmental lawsuits totaling $2.4 billion. The Cree also agreed to hydroelectric plants along the Eastman River and Rupert River, subject to environmental approval. The deal guarantees the Cree jobs with the hydroelectric authority and gives them more control over **logging** and other areas of their economy. *See also* Environmental law; Hetch Hetchy Reservoir; Nuclear energy

Japanese logging

In recent decades the timber industry has intensified efforts to harvest logs from tropical, temperate, and boreal forests worldwide to meet an increasing demand for wood and wood products. Japanese companies have been particularly active in **logging** and importing timber from around the world. Because of wasteful and destructive logging practices that result from efforts to maximize corporate financial gains, those interested in reducing **deforestation** have raised many concerns about Japan's logging industry.

The world's forests, especially tropical rain forests, are rich in **species**, including plants, insects, birds, reptiles, and mammals. Many of these species exist only in very limited areas where conditions are suitable for their existence. These endangered forest dwellers provide unique and irreplaceable genetic material that can contribute to the betterment of domestic plants and animals. The forests are a valuable resource for medically useful drugs. Healthy forests stabilize watersheds by absorbing rainfall and retarding **runoff**. Mat roots help control **soil erosion**, preventing the silting of waterways and damage to reefs, fisheries, and spawning grounds.

The United Nations Food and Agriculture Organization reports tropical deforestation rates of 42 million acres (over 17 million ha) per year. More than half of the Earth's primary tropical forest area has vanished, and more than half of the remaining forest has been degraded. While Brazil contains about a third of the world's remaining **tropical rain forest**, southeast Asia is now a major supplier of tropical woods. Burma, Thailand, Laos, Vietnam, Kampuchea, Malaysia, Indonesia, Borneo, New Guinea, and the Philippines contain 20% of the world's remaining tropical forests. With current rates of deforestation, it is estimated that almost all of Southeast Asia's primary forests will be gone by the year 2010. While a number of countries make use of **rain forest** wood, Japan is the number one importer of tropical timber. Japan's imports account for about 30% of the world trade in tropical lumber.

Japan also imports large amounts of timber from temperate and boreal forests in Canada, Russia, and the United States. These three countries contain most of the remaining boreal forests, and they supply more than half of the world's industrial wood. As demand for timber continues to climb, previously undisturbed virgin forests are increasingly being used. To speed harvesting, logging roads are built to provide access, and heavy equipment is brought in to hasten work. In the process, soil is compacted, making plant re-growth difficult or impossible. Although these practices are not limited to one country, Japanese firms have been cited by environmentalists as particularly insensitive to the environmental impact of logging.

The globe's forests are sometimes referred to as the 'lungs of the planet,' exchanging **carbon dioxide** for oxygen. Critics claim that the wood harvesting industry is destroying this vital natural resource, and in the process this industry is endangering the planet's ability to nurture and sustain life. Widespread destruction of the world's forests is a growing concern. Large Japanese companies, and companies affiliated with Japanese firms, have logged old growth forests in several parts of the globe to supply timber for the Japanese forest products industry. **Clear-cutting** of trees over large areas in tropical rain forests has made preservation of the original **flora** and **fauna** impossible. Many species are becoming extinct. Replanting may in time restore the trees, but it will not restore the array of organisms that were present in the original forest.

Large scale logging activities have had a largely negative impact on the local economies in exporting regions because whole logs are shipped to Japan for further processing. Developed countries such as the United States and Canada, which in the past harvested timber and processed it into lumber and other products, have lost jobs to Japan. Indigenous cultures that have thrived in harmony with their forest homelands for eons are displaced and destroyed. Provision has not been made for the survival of local flora and fauna, and provision for forest re-establishment has thus far proven inadequate. As resentment has grown in impacted areas, and among environmentalists, efforts have emerged to limit or stop large-scale timber harvesting and exporting.

Although concern has been voiced over all large-scale logging operations, special concern has been raised over harvesting of tropical timber from previously undisturbed primary forest areas. Tropical rain forests are especially unique and valuable **natural resources** for many reasons, including the density and variety of species within their borders. The exploitation of these unique ecosystems will result in the **extinction** of many potentially valuable species of plants and animals that exist nowhere else. Many of these forms of life have not yet been named or scientifically studied. In addition, over-harvesting of tropical rainforests has a negative effect on weather patterns, especially by reducing rainfall.

Japan is a major importer of tropical timber from Malaysia, New Guinea, and the Solomon Islands. Although the number of imported logs has declined in recent years, this has been matched by an increase in imported tropical plywood manufactured in Indonesia and Malaysia. As a result, the total amount of timber removed has remained fairly constant. An environmentalist group called the **Rainforest Action Network** (RAN) has issued an alarm concerning recent expansion of logging activity by firms affiliated with Japanese importers. The RAN alleges that: "After laying waste to the rain forests of Asia and the Pacific islands, giant Malaysian logging companies are setting their sights on the Amazon. This past year, some of Southeast Asia's biggest forestry conglomerates have moved into Brazil, and are buying controlling interests in area logging companies, and purchasing rights to cut down vast rain forest territories for as little as $3 U.S. dollars per acre. In the last few months of 1996 these companies quadrupled their South American interests, and now threaten 15% of the Amazon with immediate logging. According to *The Wall Street Journal*, up to 30 million acres (12.3 million ha) are at stake. Major players include the WTK Group, Samling, Mingo, and Rimbunan Hijau."

The RAN claims that "the same timber companies in Sarawak, Malaysia, worked with such rapacious speed that they devastated the region's forest within a decade, displacing traditional peoples and leaving the landscape marred with silted rivers and eroded soil."

One large Japanese firm, the Mitsubishi Corporation, has been targeted for criticism and boycott by the RAN, as one of the world's largest importers of timber. The boycott is an effort to encourage environmentally-conscious consumers to stop buying products marketed by companies affiliated with the huge conglomerate, including automobiles, cameras, beer, cell phones, and consumer electronics equipment. Through its subsidiaries, Mitsubishi has logged or imported timber from the Philippines, Malaysia, Papua New Guinea, Bolivia, Indonesia, Brazil, Chile, Canada (British Columbia and Alberta), Siberia, and the United States (Alaska, Oregon, Washington, and Texas). The RAN charges that "Mitsubishi Corporation is one of the most voracious destroyers of the world's rain forests. Its timber purchases have laid waste to forests in the Philippines, Malaysia, Papua New Guinea, Indonesia, Brazil, Bolivia, **Australia**, New Zealand, Siberia, Canada, and even the United States." The Mitsubishi Corporation itself does not sell consumer products, but it consists of 190 interlinked companies and hundreds of associated firms that do market to consumers. This conglomerate forms one of the world's largest industrial and financial powers. The Mitsubishi umbrella includes Mitsubishi Bank, Mitsubishi Heavy Industries, Mitsubishi Electronics, Mitsubishi Motors, and other major components. To force Mitsubishi and other corporations involved with timber harvesting to operate in a more environmentally responsible way and to end "their destructive logging and trading practices," an international boycott was organized in 1990 by the World Rainforest Movement (tropical forests) and the **Taiga** Rescue Network (boreal forests).

The Mitsubishi Corporation has countered criticism by launching a program "to promote the regeneration of rain forests...in Malaysia that plants seedlings and monitors their development." In 1990, the corporation formed an Environmental Affairs Department, one of the first of its kind in Japan, to draft environmental guidelines, and coordinate corporate environmental activities. In the words of the Mitsubishi Corporation Chairman, "A business cannot continue to exist without the trust and respect of society for its environmental performance." Mitsubishi Corporation reports that they have launched a program to support experimental reforestation projects in Malaysia, Brazil, and Chile. In Malaysia, the company is working with a local agricultural university, under the guidance of a professor from Japan. About 300,000 seedlings were planted on a barren site in 1991. Within five years, the trees were over 33 feet (10 m) in height and the corporation claimed that they were "well on the way to establishing techniques for regenerating tropical forest on burnt or barren land using indigenous species." Similar projects are underway in Brazil and Chile. The company is also conducting research on sustainable management of the Amazon rain forests. In Canada, Mitsubishi Corporation has participated in a pulp project called Al-Pac to start a mill "which will supply customers in North America, Europe, and Asia," meeting "the strictest environmental standards by employing advanced, environmentally safe technology. Al-Pac harvests around 0.25% of its total area annually and all harvested areas will be reforested."

K

Kapirowitz Plateau

The Kapirowitz Plateau, a **wildlife refuge** on the northern rim of the Grand Canyon, has come to symbolize **wildlife management** gone awry, a classic case of misguided human intervention intended to help **wildlife** that ended up damaging the animals and the **environment**. The Kapirowitz is located on the **Colorado River** in northwestern Arizona, and is bounded by steep cliffs dropping down to the Kanab Canyon to the west, and the Grand and Marble canyons to the south and southeast. Because of its inaccessibility, according to naturalist James B. Trefethen, the Plateau was considered a "biological island," and its deer population "evolved in almost complete genetic isolation."

The lush grass meadows of the Kapirowitz Plateau supported a resident population of 3,000 mule deer (*Odocoileus hemionus*), which were known and renowned for their massive size and the huge antlers of the old bucks. Before the advent of Europeans, Paiute and Navajo Indians hunted on the Kapirowitz in the fall, stocking up on meat and skins for the winter. In the early 1900s, in an effort to protect and enhance the magnificent deer population of the Kapirowitz, the federal government prohibited all killing of deer, and even eliminated the predator population in the area. As a result, the deer population exploded, causing massive overbrowsing, starvation, and a drastic decline in the health and population of the herd.

In 1893, when the Kapirowitz and surrounding lands were designated the Grand Canyon **National Forest** Reserve, hundreds of thousands of sheep, cattle, and horses were grazing on the Plateau, resulting in **overgrazing**, **erosion**, and large-scale damage to the land. On November 28, 1906, President **Theodore Roosevelt** established the one million-acre (400,000-ha) Grand Canyon National Game Preserve, which provided complete protection of the Kapirowitz 's deer population. By then, however, overgrazing by livestock had destroyed much of the native vegetation and changed the Kapirowitz considerably for the worse. Continued pasturing of over 16,000 horses and cattle degraded the Kapirowitz even further.

The **Forest Service** carried out President Roosevelt's directive to emphasize "the propagation and breeding" of the mule deer by not only banning **hunting**, but also natural predators as well. From 1906 to 1931, federal agents poisoned, shot, or trapped 4,889 coyotes (*Canis latrans*), 781 mountain lions (*Puma concolor*, 554 bobcats (*Felis rufus*), and 20 **wolves** (*Canis lupus*). Without predators to remove the old, the sick, the unwary, and other biologically unfit animals, and keep the size of the herd in check, the deer herd began to grow out of control, and to lose those qualities that made its members such unique and magnificent animals. After 1906, the deer population doubled within 10 breeding seasons, and by 1918 (two years later), it doubled again. By 1923, the herd had mushroomed to at least 30,000 deer, and perhaps as many as 100,000 according to some estimates.

Unable to support the overpopulation of deer, range grasses and land greatly deteriorated, and by 1925, 10,000–15,000 deer were reported to have died from starvation and malnutrition. Finally, after relocation efforts mostly failed to move a significant number of deer off of the Kapirowitz, hunting was reinstated, and livestock grazing was strictly controlled. By 1931, hunting, disease, and starvation had reduced the herd to under 20,000. The range grasses and other vegetation returned, and the Kapirowitz began to recover. In 1975 James Trefethen wrote, "the Kapirowitz today again produces some of the largest and heaviest antlered mule deer in North America."

In the fields of wildlife management and biology, the lessons of the Kapirowitz Plateau are often cited (as in the writings of naturalist **Aldo Leopold**) to demonstrate the valuable role of predators in maintaining the **balance of nature** (such as between herbivores and the plants they consume) and survival of the fittest. The experience of the Kapirowitz shows that in the absence of natural predators, prey populations (especially ungulates) tend to increase beyond the **carrying capacity** of the land, and eventually the

results are overpopulation and malnutrition. *See also* Predator control; Predator-prey interactions

Robert Francis Kennedy Jr. (1954 –)

American environmental lawyer

Robert "Bobby" Kennedy Jr. had a very controversial youth. Kennedy entered a drug **rehabilitation** program, at the age of 28, after being found guilty of drug possession following the South Dakota incident. He was sentenced to two years probation and community service.

Clearly the incident was a turning point in Bobby's life. "Let's just say, I had a tumultuous adolescence that lasted until I was 29," he told a reporter for New York magazine, which ran a long profile of Kennedy in 1995, entitled "Nature Boy." The title refers to the passion which has enabled Kennedy to emerge from his bleak years as a strong and vital participant in environmental causes.

A Harvard graduate and published author, Kennedy serves as chief prosecuting attorney for a group called the Hudson Riverkeeper (named after the famed New York river) and senior attorney for the **Natural Resources Defense Council**. Kennedy, who earlier in his career served as assistant district attorney in New York City after passing the bar, is also a clinical professor and supervising attorney at the Environmental Litigation Clinic at Pace University School of Law in New York.

While Kennedy appeared to be following in the family's political footsteps, working, for example, on several political campaigns and serving as a state coordinator for his Uncle Ted's 1980 presidential campaign, it is in environmental issues that Bobby Jr. has found himself. He has worked on environmental issues across the Americas and has assisted several indigenous tribes in Latin America and Canada in successfully negotiating treaties protecting traditional homelands. He is also credited with leading the fight to protect New York City's water supply, a battle which resulted in the New York City **Watershed** Agreement, regarded as an international model for combining development and environmental concerns.

Opportunity was always around the corner for a young, confident and intelligent Kennedy. After Harvard, Bobby Jr. earned a law degree at the University of Virginia. In 1978, the subject of Kennedy's Harvard thesis—a prominent Alabama judge—was named head of the FBI. A publisher offered Bobby money to expand his previous research into a book, published in 1978, called Judge Frank M. Johnson, Jr.: A Biography.

Bobby did a publicity tour which included TV appearances, but the reviews were mixed. In 1982, Bobby married Emily Black, a Protestant who later converted to Catholicism. Two children followed: Robert Francis Kennedy III and Kathleen Alexandra, named for Bobby's Aunt Kathleen, who died in a plane crash in 1948.

The marriage, however, coincided with Bobby's fallout through drug addiction. In 1992, Bobby and Emily separated, and a divorce was obtained in the Dominican Republic. In 1994, Bobby married Mary Richardson, an architect, with whom he would have two more children.

During this time Bobby emerged as a leading environmental activist and litigator. Kennedy is quoted as saying: "To me...this is a struggle of good and evil between short-term greed and a long-term vision of building communities that are dignified and enriching and that meet the obligations of **future generations**. There are two visions of America. One is that this is just a place where you make a pile for yourself and keep moving. And the other is that you put down roots and build communities that are examples to the rest of humanity." Kennedy goes on: "The **environment** cannot be separated from the economy, housing, civil rights. How we distribute the goods of the earth is the best measure of our democracy. It's not about advocating for fishes and birds. It's about human rights."

Kepone

Kepone ($C_{10}Cl_{10}O$) is an organochlorine **pesticide** that was manufactured by the Allied Chemical Corporation in Vir-

ginia from the late 1940s to the 1970s. Kepone was responsible for human health problems and extensive contamination of the James River and its **estuary** in the **Chesapeake Bay**. It is a milestone in the development of a public environmental consciousness, and its history is considered by many to be a classic example of negligent corporate behavior and inadequate oversight by state and federal agencies.

Kepone is an insecticide and **fungicide** that is closely related to other chlorinated pesticides such as DDT and aldrin. As with all such pesticides, Kepone causes lethal damage to the nervous systems of its target organisms. A poorly water-soluble substance, it can be absorbed through the skin, and it bioaccumulates in fatty tissues from which it is later released into the bloodstream. It is also a contact poison; when inhaled, absorbed, or ingested by humans, it can damage the central nervous system as well as the liver and kidneys. It can also lead to neurological symptoms such as tremors, muscle spasms, sterility, and **cancer**. Although the manufacture and use of Kepone is now banned by the **Environmental Protection Agency** (EPA), organochlorines have long half-lives, and these compounds, along with their residues and degradation products, can persist in the **environment** over many decades.

Allied Chemical first opened a plant to manufacture nitrogen-based fertilizers in 1928 in the town of Hopewell, on the banks of the James River in Virginia. This plant began producing Kepone in 1949. Commercial production was subsequently begun, although a battery of toxicity tests indicated that Kepone was both toxic and carcinogenic and that it caused damage to the functioning of the nervous, muscular, and reproductive systems in fish, birds, and mammals. It was patented by Allied in 1952 and registered with federal agencies in 1957. The demand for the pesticide grew after 1958, and Allied expanded production by entering into a variety of subcontracting agreements with a number of smaller companies, including the Life Science Products Company.

In 1970, a series of new environmental regulations came into effect which should have changed the way wastes from the manufacture of Kepone were discharged. The Refuse Act Permit Program and the National Pollutant **Discharge** Elimination Program (NPDES) of the **Clean Water Act** required all dischargers of effluents into United States waters to register their discharges and obtain permits from federal agencies. At the time these regulations went into effect, Allied Chemical had three pipes discharging Kepone and plastic wastes into the Gravelly Run, a tributary of the James River, about 75 mi (120 km) north of Chesapeake Bay.

A regional **sewage treatment** plant which would accept industrial wastes was then under construction but not scheduled for completion until 1975. Rather than installing expensive **pollution control** equipment for the interim period, Allied chose to delay. They adopted a strategy of misinformation, reporting the releases as temporary and unmonitored discharges, and they did not disclose the presence of untreated Kepone and other process wastes in the effluents. The Life Science Products Company also avoided the new federal permit requirements by discharging their wastes directly into the local Hopewell sewer system. These discharges caused problems with the functioning of the biological treatment systems at the sewage plant; the company was required to reduce concentrations of Kepone in sewage, but it continued its discharges at high concentrations, violating these standards with the apparent knowledge of plant treatment officials.

During this same period, an employee of Life Science Products visited a local Hopewell physician, complaining of tremors, weight loss, and general aches and pains. The physician discovered impaired liver and nervous functions, and a blood test revealed an astronomically high level of Kepone—7.5 **parts per million**. Federal and state officials were contacted, and the epidemiologist for the state of Virginia toured the manufacturing facility at Life Science Products. This official reported that "Kepone was everywhere in the plant," and that workers wore no protective equipment and were "virtually swimming in the stuff." Another investigation discovered 75 cases of Kepone **poisoning** among the workers; some members of their families were also found to have elevated concentrations of the chemical in their blood. Further investigations revealed that the environment around the plant was also heavily contaminated. The **soil** contained 10,000–20,000 ppm of Kepone. Sediments in the James River, as well as local landfills and trenches around the Allied facilities were just as badly contaminated. Government agencies were forced to close 100 mi (161 km) of the James River and its tributaries to commercial and recreational fishing and shellfishing.

In the middle of 1975, Life Science Products finally closed its manufacturing facility. It has been estimated that since 1966, it and Allied together produced 3.2 million lb (1.5 million kg) of Kepone and were responsible for releasing 100,000–200,000 lb (45,360–90,700 kg) into the environment. In 1976, the Northern District of Virginia filed criminal charges against Allied, Life Science Products, the city of Hopewell, and six individuals on 1,097 counts relating to the production and disposal of Kepone. The indictments were based on violations of the permit regulations, unlawful discharge into the sewer systems, and conspiracy related to that discharge.

The case went to trial without a jury. The corporations and the individuals named in the charges negotiated lighter fines and sentences by entering pleas of "no contest." Allied ultimately paid a fine of 13.3 million dollars, although their annual sales reach three billion dollars. Life Science Products

was fined four million dollars, which it could not pay due to lack of assets. Company officers were fined 25,000 dollars each, and the town of Hopewell was fined 10,000 dollars. No one was sentenced to a jail term. Civil suits brought against Allied and the other defendants resulted in a settlement of 5.25 million dollars to pay for cleanup expenses and to repair the damage that had been done to the sewage treatment plant. Allied paid another three million dollars to settle civil suits brought by workers for damage to their health.

Environmentalists and many others considered the results of legal action against the manufacturers of Kepone unsatisfactory. Some have argued that these results are typical of environmental litigation. It is difficult to establish criminal intent beyond a reasonable doubt in such cases, and even when guilt is determined, sentencing is relatively light. Corporations are rarely fined in amounts that affect their financial strength, and individual officers are almost never sent to jail. Corporate fines are generally passed along as costs to the consumer, and public bodies are treated even more lightly, since it is recognized that the fines levied on public agencies are paid by taxpayers.

Today, the James River has been reopened to fishing for those **species** that are not prone to the **bioaccumulation** of Kepone. Nevertheless, sediments in the river and its estuary contain large amounts of deposited Kepone which is released during periods of turbulence. Scientists have published studies which document that Kepone is still moving through the **food chain/web** and the **ecosystem** in this area, and Kepone toxicity has been demonstrated in a variety of invertebrate test species. There are still deposits of Kepone in the local sewer pipes in Hopewell; these continue to release the chemical, endangering treatment plant operations and polluting receiving waters.

Kesterson National Wildlife Refuge

One of a dwindling number of freshwater marshes in California's San Joaquin Valley, Kesterson **National Wildlife Refuge** achieved national notoriety in 1983 when refuge managers discovered that agricultural **runoff** was **poisoning** the area's birds. Among other elements and **agricultural chemicals** reaching toxic concentrations in the **wetlands**, the naturally occurring element selenium was identified as the cause of falling fertility and severe **birth defects** in the refuge's breeding populations of stilts, grebes, shovellers, coots, and other aquatic birds. Selenium, **lead**, boron, chromium, molybdenum, and numerous other contaminants were accumulating in refuge waters because the refuge had become an evaporation pond for tainted water draining from the region's fields.

Breeding populations of American coots were affected by selenium poisoning at Kesterson National Wildlife Refuge. (Photograph by Leonard Lee Rue III. Visuals Unlimited. Reproduced by permission.)

The soils of the **arid** San Joaquin valley are the source of Kesterson's problems. The flat valley floor is composed of ancient sea bed sediments that contain high levels of trace elements, **heavy metals**, and salts. But with generous applications of water, this sun-baked **soil** provides an excellent medium for food production. Perforated pipes buried in the fields drain away excess water—and with it dissolved salts and trace elements—after flood **irrigation**. An extensive system of underground piping, known as tile **drainage**, carries **wastewater** into a network of canals that lead to Kesterson Refuge, an artificial basin constructed by the **Bureau of Reclamation** to store irrigation runoff from central California's heavily-watered agriculture. Originally a final drainage canal from Kesterson to San Francisco Bay was planned, but because an outfall point was never agreed upon, contaminated drainage water remained trapped in Kester-

son's 12 shallow ponds. In small doses, selenium and other trace elements are not harmful and can even be dietary necessities. But steady evaporation in the refuge gradually concentrated these contaminants to dangerous levels.

Wetlands in California's San Joaquin valley were once numerous, supporting huge populations of breeding and migrating birds. In the past half century drainage and the development of agricultural fields have nearly depleted the area's marshes. The new ponds and cattail marshes at Kesterson presented a rare opportunity to extend breeding **habitat**, and the area was declared a national **wildlife refuge** in 1972, one year after the basins were constructed. Eleven years later, in the spring of 1983, observers discovered that a shocking 60% of Kesterson's nestlings were grotesquely deformed. High concentrations of selenium were found in their tissues, an inheritance from parent birds who ate algae, plants, and insects—all tainted with selenium—in the marsh.

Following extensive public outcry the local water management district agreed to try to protect the birds. Alternate drainage routes were established, and by 1987 much of the most contaminated drainage had been diverted from the **wildlife** refuge. The California Water Resource Control Board ordered the Bureau of **Reclamation** to drain the ponds and clean out contaminated sediments, at a cost of well over $50 million. However, these contaminants, especially in such large volumes and high concentrations, are difficult to contain, and similar problems could quickly emerge again. Furthermore, these problems are widespread. Selenium poisoning from irrigation runoff has been discovered in least nine other national wildlife refuges, all in the arid west, since it appeared at Kesterson. Researchers continue to work on affordable and effective responses to such contamination in wetlands, an increasingly rare habitat in this country.

Ketones

Ketones belong to a class of organic compounds known as carbonyls. They contain a **carbon** atom linked to an oxygen atom with a double bond (C=O). **Acetone** (dimethyl ketone) is a ketone commonly used in industrial applications. Other ketones include methyl ethyl ketone (MEK), methyl isobutyl ketone (MIBK), methyl amyl ketone (MAK), isophorone, and diacetone alcohol.

As solvents, ketones have the ability to dissolve other materials or substances, particularly polymers and adhesives. They are ingredients in lacquers, epoxies, polyurethane, nail polish remover, degreasers, and cleaning solvents. Ketones are also used in industry for the manufacture of **plastics** and composites and in pharmaceutical and photographic film manufacturing. Because they have high evaporation rates and dry quickly, they are sometimes employed in drying applications.

Some types of ketones used in industry, such as methyl isobutyl ketone and methyl ethyl ketone, are considered both hazardous air pollutants (HAP) and volatile organic compounds (VOC) by the EPA. As such, the **Clean Air Act** regulates their use.

In addition to these industrial sources, ketones are released into the **atmosphere** in **cigarette smoke** and car and truck exhaust. More "natural" environmental sources such as forest fires and volcanoes also emit ketones. Acetone, in particular is readily produced in the atmosphere during the oxidation of organic pollutants or natural emissions. Ketones (in the form of acetone, beta-hydroxybutyric **acid**, and acetoacetic acid) also occur in the human body as a byproduct of the **metabolism**, or break down, of fat.

Keystone species

Keystone **species** have a major influence on the structure of their ecological community. The profound influence of keystone species occurs because of their position and activity

within the **food chain/web**. In the sense meant here, a "major influence" means that removal of a keystone species would result in a large change in the abundance, and even the local extirpation, of one or more species in the community. This would fundamentally change the structure of the overall community in terms of species composition, productivity, and other characteristics. Such changes would have substantial effects on all of the species that are present, and could allow new species to invade the community.

The original use of the word "keystone" was in architecture. An architectural keystone is a wedge-shaped stone that is strategically located at the summit of an arch. The keystone serves to lock all other elements of the arch together, and it thereby gives the entire structure mechanical integrity. Keystone species play an analogous role in giving structure to the "architecture" of their ecological community.

The concept of keystone species was first applied to the role of certain predators (i.e., keystone predators) in their community. More recently, however, the term has been extended to refer to other so-called "strong interactors." This has been particularly true of keystone herbivores that have a relatively great influence on the species composition and relative abundance of plants in their community.

Keystone species directly exert their influence on the populations of species that they feed upon, but they also have indirect effects on species lower in the food web. Consider, for example, a hypothetical case of a keystone predator that regulates the population of a herbivore. This effect will also, of course, indirectly influence the abundance of plant species that the herbivore feeds upon. Moreover, by affecting the competitive relationships among the various species of plants in the community, the abundance of plants that the herbivore does not eat will also be indirectly affected by the keystone predator. Although keystone species exert their greatest influence on species with which they are most closely linked through feeding relationships, their influences can ramify throughout the food web.

Ecologists have documented the presence of keystone species in many types of communities. The phenomenon does not, however, appear to be universal, in that keystone species have not been identified in many ecosystems.

Predators as keystone species

The term "keystone species" was originally used by the American ecologist Robert Paine to refer to the critical influence of certain predators. His original usage of the concept was in reference to rocky intertidal communities of western North America, in which the predatory starfish *Pisaster ochraceous* prevents the mussel *Mytilus californianus* from monopolizing the available space on rocky habitats and thereby eliminating other, less-competitive herbivores and even seaweeds from the community. By feeding on mussels, which are the dominant competitor among the herbivores in the community, the starfish prevents these shellfish from achieving the **dominance** that would otherwise be possible. This permits the development of a community that is much richer in species than would occur in the absence of the predatory starfish. Paine demonstrated the keystone role of the starfish by conducting experiments in which the predator was excluded from small areas using cages. When this was done, the mussels quickly became strongly dominant in the community and eliminated virtually all other species of herbivores. Paine also showed that once mussels reached a certain size they were safe from predation by the starfish. This prevented the predator from eliminating the mussel from the community.

Sea otters (*Enhydra lutris*) of the west coast of North America are another example of a keystone predator. This species feeds heavily on sea urchins when these invertebrates are available. By greatly reducing the abundance of sea urchins, the sea otters prevent these herbivores from **overgrazing** kelps and other seaweeds in subtidal habitats. Therefore, when sea otters are abundant, urchins are not, and this allows luxurious kelp "forests" to develop. In the absence of otters, the high urchin populations can keep the kelp populations low, and the **habitat** then may develop as a rocky "barren ground." Because sea otters were trapped very intensively for their fur during the eighteenth and nineteenth centuries, they were extirpated over much of their natural range. In fact, the species had been considered extinct until the 1930s, when small populations were "discovered" off the coast of California and in the Aleutian Islands of Alaska. Thanks to effective protection from **trapping**, and deliberate reintroductions to some areas, populations of sea otters have now recovered over much of their original range. This has resulted in a natural depletion of urchin populations, and a widespread increase in the area of kelp forests.

Herbivores as Keystone Species

Some herbivorous animals have also been demonstrated to have a strong influence on the structure and productivity of their ecological community. One such example is the spruce budworm (*Choristoneura fumiferana*), a moth that occasionally irrupts in abundance and becomes an important **pest** of conifer forests in the northeastern United States and eastern Canada. The habitat of spruce budworm is mature forests dominated by balsam fir (*Abies balsamea*), white spruce (*Picea glauca*), and red spruce (*P. rubens*). This native species of moth is always present in at least small populations, but it sometimes reaches very high populations, which are known as irruptions. When budworm populations are high, many species of forest birds and small mammals occur in relatively large populations that subsist by feeding heavily on larvae of the moth. However, during irruptions of budworm most of the fir and spruce foliage is eaten by the abundant larvae, and after this happens for several years

many of the trees die. Because of damages caused to mature trees in the forest the budworm epidemic collapses, and then a successional recovery begins. The plant communities of early **succession** contain many species of plants that are uncommon in mature conifer forests. Eventually, however, another matures, conifer forest redevelops, and the cycle is primed for the occurrence of another irruption of the budworm. Clearly, spruce budworm is a good example of a keystone herbivore, because it has such a great influence on the populations of plant species in its habitat, and also on the many animal species that are predators of the budworm.

Another example of a keystone herbivore concerns snow geese (*Chen caerulescens*) in salt marshes of western Hudson Bay. In the absence of grazing by flocks of snow geese this **ecosystem** would become extensively dominated by several competitively superior species, such as the salt-marsh grass *Puccinellia phryganodes* and the sedge *Carex subspathacea*. However, vigorous feeding by the geese creates bare patches of up to several square meters in area, which can then be colonized by other species of plants. The patchy disturbance regime associated with goose grazing results in the development of a relatively complex community, which supports more species of plants than would otherwise be possible. In addition, by manuring the community with their droppings, the geese help to maintain higher rates of plant productivity than might otherwise occur. In recent years, however, large populations of snow goose have caused severe damages to the salt-marsh habitat by over-grazing. This has resulted in the development of salt-marsh "barrens" in some places, which may take years to recover.

Plants as keystone species

Some ecologists have also extended the idea of keystone species to refer to plant species that are extremely influential in their community. For example, sugar maple (*Acer saccharum*) is a competitively superior species that often strongly dominates stands of forest in eastern North America. Under these conditions most of the community-level productivity is contributed by sugar-maple trees. In addition, most of the seedlings and saplings are of sugar maple. This is because few seedlings of other species of trees are able to tolerate the stressful conditions beneath a closed sugar-maple canopy.

Other ecologists prefer to not use the idea of keystone species to refer to plants that, because of their competitive abilities, are strongly dominant in their community. Instead, these are sometimes referred to as "foundationstone species." This term reflects the facts that strongly dominant plants contribute the great bulk of the **biomass** and productivity of their community, and that they support almost all herbivores, predators, and **detritivores** that are present.

Kirtland's warbler

Kirtland's warbler (*Dendroica kirtlandii*) is an **endangered species** and one of the rarest members of the North American wood warbler family. Its entire breeding range is limited to a seven-county area of north-central Michigan. The restricted distribution of the Kirtland's warbler and its specific **niche** requirements have probably contributed to low population levels throughout its existence, but human activity has had a large impact on their numbers over the past hundred years.

The first specimen of Kirtland's warbler was taken by Samuel Cabot in October 1841, and brought on ship in the West Indies during an expedition to the Yucatan. But this specimen went unnoticed until 1865, long after the **species** had been formally described. Charles Pease is credited with discovering Kirtland's warbler. He collected a specimen on May 13, 1851 near Cleveland, Ohio, and gave it to his father-in-law, Dr. Jared P. Kirtland, a renowned naturalist. Kirtland sent the specimen to his friend, ornithologist Spencer Fullerton Baird, who described the new species the following year and named it in honor of the naturalist.

The wintering grounds of Kirtland's warbler is the Bahamas, a fact which was well established by the turn of the century, but its nesting grounds went undiscovered until 1903, when Norman Wood found the first nest in Oscoda County, Michigan. Every nest found since then has been within a 60 mile (95 km) radius of this spot.

In 1951 the first exhaustive census of singing males was undertaken in an effort to establish the range of Kirtland's warblers as well as its population level. Assuming that numbers of males and females are approximately equal and that a singing male is defending an active nesting site, the total of 432 in this census indicated a population of 864 birds. Ten years later another census counted 502 singing males, indicating the population was over 1,000 birds. In 1971,

annual counts began, but for the next 20 years these counts revealed that the population had dropped significantly, reaching lows of 167 singing males in 1974 and 1987. In the early 1990s, **conservation** efforts on behalf of the species began to bear fruit and the population began to recover. By 2001 the annual census counted 1,085 singing males or a total population of over 2,000 birds.

The first problem facing this endangered species centers on its specialized nesting and **habitat** requirements. The Kirtland's warbler nests on the ground, and its reproductive success is tied closely to its selection of young jack pine trees as nesting sites. When the jack pines are 5–20 ft (1.5–6 m) tall, at an age of 8–20 years, their lower branches are at ground level and provide the cover this warbler needs. The life cycle of the pine, however, is dependent on forest fires, as the intense heat is needed to open the cones for seed release. The advent of fire protection in **forest management** reduced the production of the number of young trees the warblers needed and the population suffered. Once this relationship was fully understood, jack pine stands were managed for Kirtland's warbler, as well as commercial harvest, by instituting controlled burns on a 50 year rotational basis.

The second problem is the population pressures brought to bear by a nest parasite, the brown-headed cowbird (*Molothrus ater*), which lays its eggs in the nests of other songbirds. Originally a bird of open plains, it did not threaten Kirtland's warbler until Michigan was heavily deforested, thus providing it with appropriate habitat. Once established in the warbler's range, it has increasingly pressured the Kirtland's population. Cowbird chicks hatch earlier than other birds and they compete successfully with the other nestlings for nourishment. Efforts to trap and destroy this nest parasite in the warbler's range have resulted in improved reproductive success for Kirtland's warbler. *See also* Deforestation; Endangered Species Act; International Council on Bird Preservation; Rare species; Wildlife management

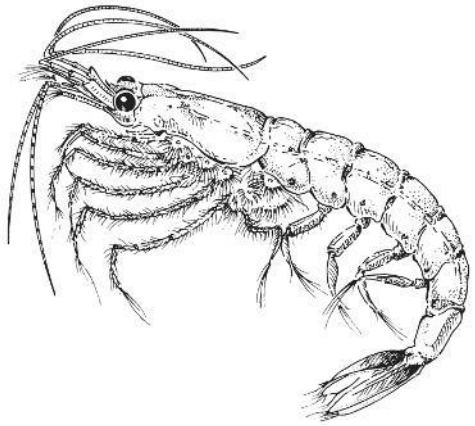
Krakatoa

The explosion of this triad of volcanoes on August 27, 1883, the culmination of a three-month eruptive phase, astonished the world because of its global impact. Perhaps one of the most influential factors, however, was its timing. It happened during a time of major growth in science, technology, and communications, and the world received current news accompanied by the correspondents' personal observations. The explosion was heard some 3,000 mi (4,828 km) away, on the Island of Rodriguez in the Indian Ocean. The glow of sunsets was so vivid three months later that fire engines were called out in New York City and nearby towns.



Krakatoa (or Krakatau), located in the Sunda Strait between Java and Sumatra, is part of the Indonesian volcanic system, which was formed by the subduction of the Indian Ocean plate under the Asian plate. A similar explosion occurred in A.D. 416, and another major eruption was recorded in 1680. Now a new **volcano** is growing out of the caldera, likely building toward some future cataclysm.

This immense natural event, perhaps twice as powerful as the largest **hydrogen** bomb, had an extraordinary impact on the solid earth, the oceans, and the **atmosphere**, and demonstrated their interdependence. It also made possible the creation of a **wildlife refuge** and **tropical rain forest** preserve on the Ujung Kulon Peninsula of southwestern Java.

Studies revealed that this caldera, like Crater Lake, Oregon, resulted from Krakatoa's collapse into the now empty magma chamber. The explosion produced a 131-ft (40-m) high tsunami, or tidal wave, which carried a steamship nearly 2 mi (3.2 km) inland, and caused most of the fatalities resulting from the eruption. Tidal gauges as far away as San Francisco Bay and the English Channel recorded fluctuations.

The explosion provided substantial benefits to the young science of **meteorology**. Every barometer on Earth recorded the blast wave as it raced towards its antipodal position in Columbia, and then reverberated back and forth in six more recorded waves. The distribution of ash in the **stratosphere** gave the first solid evidence of rapidly flowing westerly winds, as debris encircled the equator over the next 13 days. Global temperatures were lowered about 0.9°F (0.5°C), and did not return to normal until five years later.

An ironic development is that the Ujung Kulon Peninsula was never resettled after the tsunami killed most of the people. Without Krakatoa's explosion, the population would have most likely grown significantly and much of the **habitat** there would likely have been altered by agriculture. Instead, the area is now a **national park** that supports a variety of **species**, including the Javan rhino (*Rhinoceros sondaicus*), one of Earth's rarest and most **endangered species**. This park has provided a laboratory for scientists to study nature's

Krill. (McGraw-Hill Inc. Reproduced by permission.)

Krill

Marine crustaceans in the order Euphausiacea. Krill are **zooplankton**, and most feed on microalgae by filtering them from the water. In high latitudes, krill may account for a large proportion of the total zooplankton. Krill often occur in large swarms and in a few **species** these swarms may reach several hundred square meters in size with densities over 60,000 individuals per square meter. This swarming behavior makes them valuable food sources for many species of **whales** and seabirds. Humans have also begun to harvest krill for use as a dietary protein supplement.

Joseph Wood Krutch (1893 – 1970)

American literary critic and naturalist

Through much of his career, Krutch was a teacher of criticism at Columbia University and a drama critic for *The Nation*. But then respiratory problems led him to early retirement in the **desert** near Tucson, Arizona. He loved the desert and there turned to biology and geology, which he applied to maintain a consistent, major theme found in all of his writings, that of the relation of humans and the universe. Krutch subsequently became an accomplished naturalist.

Readers can find the theme of man and universe in Krutch's early work, for example *The Modern Temper* (1929), and in his later writings on human-human and human-nature relationships, including natural history—what Rene Jules Dubos described as "the social philosopher protesting against the follies committed in the name of technological progress, and the humanist searching for permanent values in man's relationship to nature." Assuming a pessimistic stance in his early writings, Krutch despaired about lost connections, arguing that for humans to reconnect, they must conceive of themselves, **nature**, "and the universe in a significant reciprocal relationship."

Krutch's later writings repudiated much of his earlier despair. He argued against the dehumanizing and alienating forces of modern society and advocated systematically reassembling—by reconnecting to nature—"a world man can live in." In *The Voice of the Desert* (1954), for instance, he claimed that "we must be part not only of the human community, but of the whole community." In such books as *The Twelve Seasons* (1949) and *The Great Chain of Life* (1956), he demonstrated that humans "are a part of Nature...whatever we discover about her we are discovering also about ourselves." This view was based on a solid anti-deterministic approach that opposed mechanistic and behavioristic theories of **evolution** and biology.

His view of modern technology as out of control was epitomized in the **automobile**. Driving fast prevented people from reflecting or thinking or doing anything except controlling the monster: "I'm afraid this is the metaphor of our society as a whole," he commented. Krutch also disliked the proliferation of suburbs, which he labeled "affluent slums." He argued in *Human Nature and the Human Condition* (1959) that "modern man should be concerned with achieving the good life, not with raising the [material] standard of living."

An editorial ran in *The New York Times* a week after Krutch's death: today's younger generation, it read, "unfamiliar with Joseph Wood Krutch but concerned about the **environment** and contemptuous of materialism," should "turn to a reading of his books with delight to themselves and profit to the world."

Kudzu

Pueraria lobata or kudzu, also jokingly referred to as "foot-a-night" and "the vine that ate the South," is a highly aggressive and persistent semi-woody vine introduced to the United States in the late nineteenth century. It has since become a symbol of the problems possible for native ecosystems caused by the introduction of **exotic species**. Kudzu's best known characteristic is its extraordinary capacity for rapid growth, managing as much as 12 in (30.5 cm) a day and 60–100 ft (18–30 m) a season under ideal conditions. When young, kudzu has thin, flexible, downy stems that grow outward as well as upward, eventually covering virtually everything in its path with a thick mat of leaves and tendrils. This lateral growth creates the dramatic effect, common in southeastern states such as Georgia, of telephone poles, buildings, neglected vehicles, and whole areas of woodland being enshrouded in blankets of kudzu. Kudzu's tendency towards aggressive and overwhelming colonization has many detrimental effects, killing stands of trees by robbing them of sunlight and pulling down or shorting out utility cables. Where stem nodes touch the ground, new roots develop which can extend 10 ft (3 m) or more underground and eventually weigh several hundred pounds. In the nearly ideal **climate** of the Southeast, the prolific vine easily overwhelms virtually all native competitors and also infests cropland and yards.

A member of the pea family, kudzu is itself native to China and Japan. Introduced to the United States at the Japanese garden pavilion during the 1876 Philadelphia Centennial Exhibition, kudzu's broad leaves and richly fragrant reddish-purple blooms made it seem highly desirable as an ornamental plant in American gardens. It now ranges along the eastern seaboard from Florida to Pennsylvania, and westward to Texas. Although hardy, kudzu does not tolerate cold weather and prefers acidic, well-drained soils and bright sunlight. It rarely flowers or sets seed in the northern part of its range and loses its leaves at first frost.

For centuries, the Japanese have cultivated kudzu for its edible roots, medicinal qualities, and fibrous leaves and stems, which are suitable for paper production. After its initial introduction as an ornamental, kudzu also was touted as a forage crop and as a cure for **erosion** in the United States. Kudzu is nutritionally comparable to alfalfa, and its tremendous durability and speed of growth were thought to outweigh the disadvantages caused for cutting and baling by its rope-like vines. But its effectiveness as a ground cover, particularly on steeply-sloped terrain, is responsible for kudzu's spectacular spread. By the 1930s, the United States **Soil Conservation Service** was enthusiastically advocating kudzu as a remedy for erosion, subsidizing farmers as well as highway departments and railroads, with as much as $8 an acre to use kudzu for **soil** retention. The Depression-era Civilian Conservation Corps also facilitated the spread of kudzu, planting millions of seedlings as part of an extensive erosion control project.

Kudzu also has had its unofficial champions, the best known of whom is Channing Cope of Covington, Georgia. As a journalist for Atlanta newspapers and popular radio broadcaster, Cope frequently extolled the virtues of kudzu, dubbing it the "miracle vine" and declaring that it had replaced cotton as "King" of the South. The spread of the vine was precipitous. In the early 1950s, the federal government began to question the wisdom of its support for kudzu. By 1953, the Department of Agriculture stopped recommending the use of kudzu for either fodder or ground cover. In 1982, kudzu was officially declared a weed.

Funding is now directed more at finding ways to eradicate kudzu or at least to contain its spread. Continuous overgrazing by livestock will eventually eradicate a field of kudzu, as will repeated applications of defoliant herbicides. Even so, stubborn patches may take five or more years to be completely removed. Controlled burning is usually ineffective and attempting to dig up the massive root system is generally an exercise in futility, but kudzu can be kept off lawns and fences (as an ongoing project) by repeated mowing and enthusiastic pruning.

A variety of new uses are being found for kudzu, and some very old uses are being rediscovered. Kudzu root can be processed into flour and baked into breads and cakes; as a starchy sweetener, it also may be used to flavor soft drinks. Medical researchers investigating the scientific bases of traditional herbal remedies have suggested that isoflavones found in kudzu root may significantly reduce craving for alcohol in alcoholics. Eventually, derivatives of kudzu may also prove to be useful for treatment of high blood pressure. **Methane** and **gasohol** have been successfully produced from kudzu, and kudzu's stems may prove to be an economically viable

source of fiber for paper production and other purposes. The prolific vine has also become something of a humorous cultural icon, with regional picture postcards throughout the south portraying spectacular and only somewhat exaggerated images of kudzu's explosive growth. Fairs, festivals, restaurants, bars, rock groups, and road races have all borrowed their name and drawn some measure of inspiration from kudzu, poems have been written about it, and kudzu cookbooks and guides to kudzu crafts are readily available in bookstores.

Kwashiorkor

One of many severe protein energy malnutrition disorders that are a widespread problem among children in developing countries. The word's origin is in Ghana, where it means a deposed child, or a child that is no longer suckled. The disease usually affects infants between one and four years of age who have been weaned from breast milk to a high starch, low protein diet. The disease is characterized by lethargy, apathy, or irritability. Over time the individual will experience retarded growth processes both physically and mentally. Approximately 25% of children suffer from recurrent relapses of kwashiorkor, interfering with their normal growth.

Kwashiorkor results in amino **acid** deficiencies which inhibit protein synthesis in all tissues. The lack of sufficient **plasma** proteins, specifically albumin, results in **systemic** pressure changes, ultimately causing generalized edema. The liver swells with stored fat because there are no hepatic proteins being produced for digestion of fats. Kwashiorkor additionally results in reduced bone density and impaired renal function. If treated early on in its development the disease can be reversed with proper dietary therapy and treatment of associated infections. If the condition is not reversed in its early stages, prognosis is poor and physical and mental growth will be severely retarded. *See also* Sahel; Third World

Kyoto Protocol/Treaty

In the mid-1980s, a growing body of scientific evidence linked man-made greenhouse gas emissions to global warming. In 1990, the United Nations General Assembly issued a report that confirmed this link. The Rio Accord of 1992 resulted from this report. Formally called the United Nations Framework Convention on Climate Change (UNFCC), the accord was signed by various nations in Rio de Janeiro, Brazil and committed industrialized nations to stabilizing their emissions at 1990 levels by 2000.

In December 1997, representatives of 160 nations met in Kyoto, Japan, in an attempt to produce a new and improved treaty on climate change. Major differences occurred between industrialized and still developing countries with the United States perceived, particularly by representatives of the **European Union** (EU), as not doing its share to reduce emissions, especially those of **carbon dioxide**.

The outcome of this meeting, the Kyoto Protocol to the United Nations Framework Convention on Climate Change (UNFCCC), required industrialized nations to reduce their emissions of **carbon** dioxide, **methane**, **nitrous oxide**, hydrofluorocarbons, sulfur dioxides, and perfluorocarbons below 1990 levels by 2012. The requirements would be different for each country and would have to begin by 2008 and be met by 2012. There would be no requirements for the developing nations. Whether or not to sign and ratify the treaty was left up to the discretion of each individual country.

Global warming

The organization that provided the research for the Kyoto Protocol was the **Intergovernmental Panel on Climate Change** (IPCC), set up in 1988 as a joint project of the **United Nations Environment Programme** (UNEP) and the World Meteorological Organization (WMO). In 2001 the IPCC released a report, "Climate Change, 2001". Using the latest climatic and atmospheric scientific research available, the report predicted that global mean surface temperatures on earth would increase by 2.5–10.4°F (1.5–5.9 °C) by the year 2100, unless greenhouse gas emissions were reduced well below current levels. This warming trend was seen as rapidly accelerating, with possible dire consequences to human society and the **environment**. These accelerating temperature changes were expected to lead to rising sea levels, melting glaciers and polar ice packs, heat waves, droughts and wildfires, and a profound and deleterious effect on human health and well-being.

Some of the effects of these temperature changes may already be occurring. Most of the United States has already experienced increases in mean annual temperature of up to 4°F (2.3°C). Sea ice is melting in both the **Antarctica** and the Arctic. Ninety-eight percent of the world's glaciers are

shrinking. The sea level is rising at three times its historic rate. Florida is already feeling the early effects of global warming with shorelines suffering from **erosion**, with dying coral reefs, with saltwater polluting the fresh water sources, with an increase in wildfires, and with higher air and water temperatures. In Canada, forest fires have more than doubled since 1970, water **wells** are going dry, lake levels are down, and there is less rainfall.

Controversy

Since its inception, the Kyoto Protocol has generated a great deal of controversy. Richer nations have argued that the poorer, less developed nations are getting off easy. The developing nations, on the other hand, have argued that they will never be able to catch up with the richer nations unless they are allowed to develop with the same degree of **pollution** as that which let the industrial nations become rich in the first place.

Another controversy rages between environmentalists and big business. Environmentalists have argued that the Kyoto Protocol doesn't go far enough, while **petroleum** and industry spokespersons have argued that it would be impossible to implement without economic disaster.

In the United States, the controversy has waxed especially high. The Kyoto Protocol was signed under the administration of President Bill Clinton, but was never ratified by the Republican-dominated U.S. Senate. Then in 2001, President George W. Bush, a former Texas oilman, backed out of the treaty, saying it would cost the U.S. economy 400 billion dollars and 4.9 million jobs. Bush unveiled an alternative proposal to the Kyoto accord that he said would reduce **greenhouse gases**, curb pollution and promote **energy efficiency**. But critics of his plan have argued that by the year 2012 it would actually increase the 1990 levels of greenhouse gas emissions by more than 30%.

Soon after the Kyoto Protocol was rejected by the Bush administration, the European Union criticized the action. In particular, Germany was unable to understand why the Kyoto restrictions would adversely effect the American economy, noting that Germany had been able to reduce their emissions without serious economic problems. The Germans also suggested that President Bush's program to induce voluntary reductions was politically motivated and was designed to prevent a drop in the unreasonably high level of consumption of greenhouse gases in the United States, a drop that would be politically damaging for the Bush administration.

In rejecting the Kyoto Protocol, President Bush claimed that it would place an unfair burden on the United States. He argued that it was unfair that developing countries such as India and China should be exempt. But China had already taken major steps to affect climate change. According to a June report by the **World Resources Institute**, a Washington, D.C.-based environmental think tank, China voluntarily cut its carbon dioxide emissions by 19% between 1997 and 1999. Contrary to Bush's fears that cutting carbon dioxide output would inevitably damage the United States economy, China's economy grew by 15% during this same two-year period.

Politics has always been at the forefront of this debate. The IPCC has provided assessments of climate change that have helped shape international treaties, including the Kyoto Protocol. However, the Bush administration, acting at the request of ExxonMobil, the world's largest oil company, and attempting to cast doubts upon the scientific integrity of the IPCC, was behind the ouster in 2002 of IPCC chairperson Robert Watson, an atmospheric scientist who supported implementing actions against global warming.

The ability of trees and plants to fix carbon through the process of **photosynthesis**, a process called *carbon or C sequestration*, results in a large amount of carbon stored in **biomass** around the world. In the framework of the Kyoto Protocol, C sequestration to mitigate the **greenhouse effect** in the terrestrial **ecosystem** has been an important topic of discussion in numerous recent international meetings and reports. To increase C sequestration in soils in the dryland and tropical areas, as a contribution to global reductions of atmospheric CO_2, the United States has promoted new strategies and new practices in agriculture, pasture use and forestry, including **conservation** agriculture and **agroforestry**. Such practices should be facilitated particularly by the application of article 3.4 of the Kyoto Protocol covering the additional activities in agriculture and forestry in the developing countries and by appropriate policies.

Into the future

In June 2002, the 15 member nations of the European Union formally signed the Kyoto Protocol. The ratification by the 15 EU countries was a major step toward making the 1997 treaty effective. Soon after, Japan signed the treaty, and Russia was expected to follow suit.

To take effect, the Kyoto Protocol must be ratified by 55 countries, but these ratifications have to include industrialized nations responsible for at least 55% of the 1990 levels of greenhouse gases. As of 2002, over 70 countries had already signed, exceeding the minimum number of countries needed. If Russia signs the treaty, nations responsible for over 55% of the 1990 levels of greenhouse gas pollution will have signed, and the Kyoto Protocol will take effect.

Before the EU ratified the protocol, the vast majority of countries that had ratified were developing countries. With the withdrawal of the United States, responsible for 36.1% of greenhouse gas emissions in 1990, ratification by industrialized nations was crucial. For example, environmentalists hope that Canada will ratify the treaty as it has already committed compliance.

Although the Bush administration opposed the Kyoto Protocol, saying that its own plan of voluntary restrictions would work as well without the loss of billions of dollars and without driving millions of Americans out of work, the EPA, under its administrator Christine Todd Whitman, in 2002 sent a climate report to the United Nations detailing specific, far-reaching, and disastrous effects of global warming upon the American environment and its people. The EPA report also admitted that global warming is occurring because of man-made carbon dioxide and other greenhouse gases. However, it offered no major changes in administration policies, instead recommending adapting to the inevitable and catastrophic changes.

Although the United States was still resisting the Kyoto Protocol in mid-2002, and the treaty's implications for radical and effective action, various states and communities decided to go it alone. Massachusetts and New Hampshire enacted legislation to cut carbon emissions. California was considering legislation limiting emissions from cars and small trucks. Over 100 U.S. cities had already opted to cut carbon emissions. Even the U.S business community, because of their many overseas operations, was beginning to voluntarily cut back on their greenhouse emissions.

La Niña

La Niña, Spanish for "the little girl," is also called a cold episode, "El Viejo" (The Old Man), or anti-El Niño. It is one of two major changes in the Pacific Ocean surface temperature that affect global weather patterns. La Niña and **El Niño** ("the little boy") are the extreme phases of the El Niño/Southern Oscillation, a **climate** cycle that occurs naturally in the eastern tropical Pacific Ocean. The effects of both phases are usually strongest from December to March. In some ways, La Niña is the opposite of El Niño. For example, La Niña usually brings more rain to **Australia** and Indonesia, areas that are susceptible to **drought** during El Niño.

La Niña is characterized by unusually cold ocean surface temperatures in the equatorial region. Ordinarily, the sea surface temperature off the western coast of South America ranges from 60–70°F (15–21°C). According to the **National Oceanic and Atmospheric Administration** (NOAA), the temperature dropped by up to 7°F (4°C) below normal during the 1988–1989 La Niña. In the United States, La Niña usually brings cooler and wetter than normal conditions in the Pacific Northwest and warmer and drier conditions in the Southeast. In contrast, during El Niño, surface water temperatures in the tropical Pacific are unusually warm. Because water temperatures increase around Christmas, people in South America called the condition "El Niño" to honor the Christ Child.

The two weather phenomena are caused by the interaction of the ocean surface and the **atmosphere** in the tropical Pacific. Changes in the ocean affect the atmosphere and climate patterns around the world, with changes in the atmosphere in turn affecting the ocean temperature and currents. Before the onset of La Niña, there is usually a build-up of cooler than normal subsurface water in the tropical Pacific. The cold water is brought to the surface by atmospheric waves and ocean waves. Winds and currents push warm water towards Asia. In addition, the system can drive the polar jet stream (a stream of winds at high altitude) to the north; this affects weather in the United States.

The effects of La Niña and El Niño are generally seen in the United States during the winter. The two conditions usually occur every three to five years. However, the period between episodes may be from two to seven years. The conditions generally last from nine to 12 months, but episodes could last as long as two years.

Since 1975, El Niños have occurred twice as frequently as La Niñas. While both conditions are cyclical, a La Niña episode does not always follow an El Niño episode. La Niñas in the twentieth century occurred in 1904, 1908, 1910, 1916, 1924, 1928, 1938, 1950, 1955, 1964, 1970, 1973, 1975, 1988, 1995, and 1998. Effects of the 1998 La Niña included **flooding** in Mozambique in 2000 and a record warm winter in the United States. Nationwide temperatures averaged 38.4°F (3.5°C) from December 1999 through February 2000, according to the NOAA. In addition, that three-month period was the sixteenth driest winter in the 105 years that records have been kept by National Climatic Data Center. The 1998 La Niña was diminishing by November 2000; another La Niña had not been projected as of May 2002.

Scientists from the NOAA and other agencies use various tools to monitor La Niña and El Niño. These tools include satellites and data buoys that are used to monitor sea surface temperatures. Tracking the two weather phenomena can help nations to prepare for potential disasters such as floods. In addition, knowledge of the systems can help businesses plan for the future. In a March 1999 article in *Nation's Restaurant News*, writer John T. Barone described the impact that La Niña could have on food and beverage prices. Barone projected that drought conditions in Brazil could bring an increase in the price of coffee.

La Paz Agreement

The 1983 La Paz Agreement between the United States and Mexico is a pact to protect, conserve, and improve the **environment** of the border region of both countries. The agreement defined the region as the 62 mi (100 km) to the north and south of the international border. This area includes maritime (sea) boundaries and land in four American states and six Mexican border states.

Representatives from the two countries signed the agreement on Aug. 14, 1983, in La Paz, Mexico. The agreement took effect on Feb. 16, 1984. It established six workgroups, with each group concentrating on an environmental concern. Representatives from both countries serve on the workgroups that focus on water, air, hazardous and **solid waste**, **pollution** prevention, contingency planning and emergency response, and cooperative enforcement and compliance.

In February of 1992, environmental officials from the two countries released the Integrated Environmental Plan for the Mexican-U.S. Border Area. The Border XXI Program created nine additional workgroups. These groups focus on environmental information resources, **natural resources**, and **environmental health**.

Border XXI involves federal, state, and local governments on both sides of the border. Residents also participate through activities such as public hearings.

Lagoon

A lagoon is a shallow body of water separated from a larger, open body of water. It is typically associated with the ocean, such as coastal lagoons and **coral reef** lagoons. Lagoon also can be used to describe shallow areas of liquid waste material as in sewage lagoons. Oceanic lagoons can be formed in several ways. Coastal lagoons are typically found along coastlines where there are sand bars or barrier islands that separate the open ocean from the near shore body of water. Coral reef lagoons can form in two ways. The first type is found in barrier reefs such as those in **Australia** and Belize, where there is a body of water (lagoon) which is separated from the open ocean by the reef formed many miles off shore. Another type of lagoon is that formed in the center of atolls, which are circular or horse-shoe shaped bodies of water in the middle of partially sunken volcanic islands with coral reefs growing around their periphery. Some of these atoll lagoons are more than 30 mi (50 km) across and have breathtaking **visibility**, thus providing superb sites for SCUBA diving.

Lake Baikal

The **Great Lakes** are a prominent feature of the North American landscape, but Russia holds the distinction of having the "World's Great Lake." Called the "Pearl of Siberia" or the "Sacred Sea" by locals, Lake Baikal is the world's deepest and largest lake by volume. It has a surface area of 12,162 sq miles (31,500 sq km), a maximum depth of 5,370 ft (1,637 m), or slightly more than 1 mile, an average depth of 2,428 ft (740 m), and a volume of 30,061 cu yd (23,000 cu m). It thus contains more water than the combined volume of all of the North American Great Lakes—20 percent of the world's fresh water (and 80 percent of the fresh water of the former Soviet Union).

Lake Baikal is located in Russia in south-central Siberia near the northern border of Mongolia. Scientists estimate that the lake was formed 25 million years ago by tectonic (**earthquake**) displacement, creating a crescent-shaped, steep-walled basin 395 miles (635 km) long by 50 miles (80 km) wide and nearly 5.6 miles (9 km) deep. In contrast, the Great Lakes were formed by glacial scouring a mere 10,000 years ago.

Although **sedimentation** has filled in 80 percent of the basin over the years, the lake is believed to be widening and deepening ever so slightly with time because of recurring crustal movements. The area surrounding Lake Baikal is underridden by at least three crustal plates, causing frequent earthquakes. Fortunately, most are too weak to feel.

Like similarly ancient Lake Tanganyika in Africa, the waters of Lake Baikal host a great number of unique **species**. Of the 1,200 known animal and 600 known plant species, more than 80 percent are endemic to this lake. These include many species of fish, shrimp, and the world's only fresh water sponges and **seals**. Called *nerpa* or *nerpy* by the natives, these seals (*Phoca sibirica*) are silvery-gray in color and can grow to 5 ft (1.5 m) long and weigh up to 286 lb (130 kg). Their diet consists almost exclusively of a strange-looking relict fish called *golomyanka* (*Comephorus baicalensis*), ren-

A view of the Strait of Olkhon, on the west coast of Lake Baikal, Russia. (Photograph by Press Agency, Science Photo Library. Photo Researchers Inc. Reproduced by permission.)

dered translucent by its fat-filled body. Unlike other fish, they lack scales and swim bladders and give birth to live larvae rather than eggs. The seal population is estimated at 60,000. Commercial hunters are permitted to kill 6,000 each year.

Although the waters of Lake Baikal are pristine by the standards of other large lakes, increased **pollution** threatens its future. Towns along its shores and along the stretches of the Selenga River, the major tributary flowing into Baikal, add human and industrial wastes, some of which is nonbiodegradable and some highly toxic. A hydroelectric dam on the Angara River, the lake's only outlet, raised the water level and placed spawning areas of some fish below the optimum depth. Most controversial to the people who depend on this lake for their livelihood and pleasure, however, was the construction of a large cellulose plant at the southern end near the city of Baikalsk in 1957. Built originally to manufacture high-quality aircraft tires (ironically, synthetic tires proved superior), today it produces clothing from bleached cellulose and employs 3,500 people. Uncharacteristic public outcry over the years has resulted in the addition of advanced **sewage treatment** facilities to the plant. Although some people would like to see it shut down, the local (and national) economy has taken precedence.

In 1987 the Soviet government passed legislation protecting Lake Baikal from further destruction. **Logging** was prohibited anywhere close to the shoreline and **nature** reserves and national parks were designated. However, with the recent political turmoil and crippling financial situation in the former Soviet Union, these changes have not been enforced and the lake continues to receive pollutants. Much more needs to be done to assure the future of this magnificent lake. *See also* Endemic species

Lake Erie

Lake Erie is the most productive of the **Great Lakes**. Located along the southern fringe of the Precambrian Shield of North America, Lake Erie has been ecologically degraded by a variety of **anthropogenic** stressors including **nutrient loading**; extensive **deforestation** of its **watershed** that caused severe **siltation** and other effects; vigorous **commercial fishing**; and **pollution** by toxic **chemicals**.

The watershed of Lake Erie is much more agricultural and urban in character than are those of the other Great Lakes. Consequently, the dominant sources of **phosphorus** (the most important nutrient causing eutrophication) to Lake Erie are agricultural **runoff** and municipal point sources. The total input of phosphorus to Lake Erie (standardized to watershed area) is about l.3 times larger than to Lake Ontario and more than five times larger than to the other Great Lakes.

Because of its large loading rates and concentrations of nutrients, Lake Erie is more productive and has a larger standing crop of **phytoplankton**, fish, and other biota than the other Great Lakes. During the late 1960s and early 1970s, the eutrophic western basin of Lake Erie had a summer-chlorophyll concentration averaging twice as large as in Lake Ontario and 11 times larger than in **oligotrophic** Lake Superior. However, since that time the eutrophication of Lake Erie has been alleviated somewhat, in direct response to decreased phosphorus inputs with sewage and **detergents**. A consequence of the eutrophic state of Lake Erie was the development of anoxia (lack of oxygen) in its deeper waters during summer **stratification**. In the summer of 1953, this condition caused a collapse of the population of benthic mayfly larvae (*Hexagenia* spp.), a phenomenon that was interpreted in the popular press as the "death" of Lake Erie.

Large changes have also taken place in the fish community of Lake Erie, mostly because of its fishery, the damming of streams required for spawning by anadromous fishes (fish that ascend rivers or streams to spawn), and **sedimentation** of shallow-water **habitat** by **silt** eroded from deforested parts of the watershed. Lake Erie has always had the most productive fishery on the Great Lakes, with fish landings that typically exceed the combined totals of all the other Great Lakes. The peak years of commercial fishery in Lake Erie were in 1935 and 1956 (62 million lb/28 million kg), while the minima were in 1929 and 1941 (24 million lb/11 million kg). Overall, the total catch by the commercial fishery has been remarkably stable over time, despite large changes in **species**, effort, eutrophication, toxic pollution, and other changes in habitat.

The historical pattern of development of the Lake Erie fishery was characterized by an initial exploitation of the most desirable and valuable species. As the populations of these species collapsed because of unsustainable fishing pressure, coupled with habitat deterioration, the fishery diverted to a progression of less-desirable species. The initial fishery focused on lake white fish (*Coregonus clupeaformis*), lake trout (*Salvelinus namaycush*), and lake herring (*Leucichthys artedi*), all of which rapidly declined to **scarcity** or **extinction**. The next target was "second-choice" species, such as blue pike (*Stizostedion vitreum glaucum*) and walleye (*S. v. vitreum*), which are now extinct or rare. Today's fishery is dominated by species of much smaller economic value, such as yellow perch (*Perca flavescens*), rainbow smelt (*Osmerus mordax*), and carp (*Cyprinus carpio*).

In 1989 an invasive species—the **zebra mussel** (*Dreissena polymorpha*—reached Lake Erie and began to have a significant ecological impact on the lake. Zebra mussels are filter feeders, and each adult mussel can filter a liter of water per day, removing every microscopic plant (phytoplankton or algae) and animal (**zooplankton**) in the process. Zebra mussel densities in Lake Erie have reached such a level that the entire volume of the lake's western basin is filtered each week. This has increased water clarity up to 600 percent and reduced some forms of phytoplankton in the lake's food web by as much as 80 percent. In addition, the increased clarity of the water allows light to penetrate deeper into the water, thus facilitating the growth of rooted aquatic plants and increasing populations of some bottom-dwelling algae and tiny animals. Zebra mussels also concentrate 10 times more **toxins** than do native mussels, and these contaminants are passed up the food chain to the fish and birds that eat zebra mussels. Since **bioaccumulation** of toxins has already led to advisories against eating some species of Great Lakes fish, the contribution of zebra mussels to contaminant cycling in lake species is a serious concern. *See also* Cultural eutrophication; Water pollution

Lake Tahoe

A beautiful lake 6,200 ft (1,891 m) high in the Sierra Nevada, straddling the California-Nevada state line, Lake Tahoe is a jewel to both nature-lovers and developers. It is the tenth deepest lake in the world, with a maximum depth of 1,600 ft (488 m) and a total volume of 37 trillion gallons. At the south end of the lake sits a dam that supplies up to six feet of Lake Tahoe's water flow into the outlet of the Truckee River. The U.S. **Bureau of Reclamation** controls water diversion into the Truckee, which is used for **irrigation**, power, and recreational purposes throughout Nevada.

Tahoe and Crater Lake are the only two large alpine lakes remaining in the United States. Visitors have expressed their awe of the lake's beauty since it was discovered by General John Frémont in 1844. Mark Twain wrote that it was "the fairest sight the whole Earth affords."

The arrival of Europeans in the Tahoe area was quickly followed by environmental devastation. Between 1870 and 1900, forests around the lake were heavily logged to provide timber for the mine shafts of the Comstock Lode. While this **logging** dramatically altered the area's appearance for years, the natural **environment** eventually recovered and no long-term logging-related damage to the lake can now be detected.

The same can not be said for a later assault on the lake's environment. Shortly after World War II, people began moving into the area to take advantage of the region's natural wonders—the lake itself and superb snow skiing—as well as the young casino business on the Nevada side of the lake. The 1960 Winter Olympics, held at Squaw Valley, placed Tahoe's recreational assets in the international spotlight. Lakeside population grew from about 20,000 in 1960 to more than 65,000 today, with an estimated tourist population of 22 million annually.

The impact of this rapid **population growth** soon became apparent in the lake itself. Early records showed that the lake was once clear enough to allow **visibility** to a depth of about 130 ft (40 m). By the late 1960s, that figure had dropped to about 100 ft (30 m).

Tahoe is now undergoing eutrophication at a fairly rapid rate. Algal growth is being encouraged by sewage and **fertilizer** produced by human activities. Much of the area's natural **pollution** controls, such as trees and plants, have been removed to make room for residential and commercial development. The lack of significant flow into and out of the lake also contributes to a favorable environment for algal growth.

Efforts to protect the pristine beauty of Lake Tahoe go back at least to 1912. Three efforts were made during that decade to have the lake declared a **national park**, but all failed. By 1958, concerned conservationists had formed the Lake Tahoe Area Council to "promote the preservation and long-range development of the Lake Tahoe basin." The Council was followed by other organizations with similar objectives, the League to Save Lake Tahoe among them.

An important step in resolving the conflict between preservationists and developers occurred in 1969 with the creation of the Tahoe Regional Planning Agency (TRPA). The agency was the first and only **land use** commission with authority in more than one state. It consisted of fourteen members, seven appointed by each of the governors of the two states involved, California and Nevada. For more than a decade, the agency attempted to write a land-use plan that would be acceptable to both sides of the dispute. The conflict became more complex when the California Attorney General, John Van de Kamp, filed suit in 1985 to prevent TRPA from granting any further permits for development. Developers were outraged but lost all of their court appeals.

By 2000, the strain of tourism, development, and nonpoint **automobile** pollution was having a visible impact on Lake Tahoe's legendary deep blue surface. A study released by the University of California—Davis and the University of Nevada—Reno reported that visibility in the lake had decreased to 70 ft (21 m), an average decline of a foot a year since the 1960s. As part of a renewed effort to reverse Tahoe's environmental decline, President Clinton signed the Lake Tahoe Restoration Act into law in late 2000, authorizing $300 million towards restoration of **water quality** in Lake Tahoe over a period of 10 years. *See also* Algal bloom; Cultural eutrophication; Environmental degradation; Fish kills; Sierra Club; Water pollution

Lake Washington

One of the great messages to come out of the environmental movement of the 1960s and 1970s is that, while humans can cause **pollution**, they can also clean it up. Few success stories illustrate this point as clearly as that of Lake Washington. Lake Washington lies along the state of Washington's west coastline, near the city of Seattle. It is 24 miles (39 km) from north to south and its width varies from 2–4 miles (3–6 km).

For the first half of this century, Lake Washington was clear and pristine, a beautiful example of the Northwest's spectacular natural scenery. Its shores were occupied by extensive wooded areas and a few small towns with populations of no more than 10,000. The lake's purity was not threatened by Seattle, which dumped most of its wastes into Elliot Bay, an arm of Puget Sound. This situation changed rapidly during and after World War II. In 1940, the spectacular Lake Washington Bridge was built across the lake, joining its two facing shores with each other and with Seattle. Population along the lake began to boom, reaching more than 50,000 by 1950.

The consequence of these changes for the lake are easy to imagine. Many of the growing communities dumped their raw sewage directly into the lake or, at best, passed their wastes though only preliminary treatment stages. By one estimate, 20 million gallons (76 million liters) of wastes were being dumped into the lake each day. On average these wastes still contained about half of their pollutants when they reached the lake. In less than a decade, the effect of these practices on lake **water quality** were easy to observe. Water clarity was reduced from at least 15 ft (4.6 m) to 2.5 ft (0.8 m) and levels of **dissolved oxygen** were so low that some **species** of fish disappeared. In 1956, W. T. Edmonson, a zoologist and pollution authority, and two colleagues reported their studies of the lake. They found that eutrophication of the lake was taking place very rapidly as a result of the dumping of domestic wastes into its water.

Solving this problem was especially difficult because **water pollution** is a regional issue over which each individual community had relatively little control. The solution appeared to be the creation of a new governmental body that would encompass all of the Lake Washington communities, including Seattle. In 1958, a ballot measure establishing such an agency, known as Metro, was passed in Seattle but defeated in its suburbs. Six months later, the Metro concept was redefined to include the issue of sewage disposal only. This time it passed in all communities.

Metro's approach to the Lake Washington problem was to construct a network of sewer lines and **sewage treatment** plants that directed all sewage away from the lake and delivered it instead to Puget Sound. The lake's pollution problems were solved within a few years. By 1975 the lake was back to normal, water clarity returned to 15 ft and levels of potassium and **nitrogen** in the lake decreased by more than 60 percent. Lake Washington's biological oxygen demand (BOD), a critical measure of water purity, decreased by 90 percent and fish species that had disappeared were once again found in the lake. *See also* Aquatic chemistry; Cultural eutrophication; Waste management; Water quality standards

Land ethic

Land ethic refers to an approach to issues of **land use** that emphasizes **conservation** and respect for our natural **environment**. Rejecting the belief that all **natural resources** should be available for unchecked human exploitation, a land ethic advocates land use without undue disturbances of the complex, delicately balanced ecological systems of which humans are a part. Land ethic, **environmental ethics**, and ecological ethics are sometimes used interchangeably.

Discussions of land ethic, especially in the United States, usually begin with a reference of some kind to **Aldo Leopold**. Many participants in the debate over land and resource use admire Leopold's prescient and pioneering quest and date the beginnings of a land ethic to his *A Sand County Almanac*, published in 1949. However, Leopold's earliest

formulation of his position may be found in "A Conservation Ethic," a benchmark essay on ethics published in 1933.

Even recognizing Leopold's remarkable early contribution, it is still necessary to place his pioneer work in a larger context. Land ethic is not a radically new invention of the twentieth century but has many ancient and modern antecedents in the Western philosophical tradition. The Greek philosopher Plato, for example, wrote that morality is "the effective harmony of the whole"—not a bad statement of an ecological ethic. Reckless exploitation has at times been justified as enjoying divine sanction in the Judeo-Christian tradition (man was made master of the creation, authorized to do with it as he saw fit). However, most Christian thought through the ages has interpreted the proper human role as one of careful husbandry of resources that do not, in fact, belong to humans. In the nineteenth century, the Huxleys, Thomas and Julian, worked on relating **evolution** and ethics. The mathematician and philosopher Bertrand Russell wrote that "man is not a solitary animal, and so long as social life survives, self-realization cannot be the supreme principle of ethics." **Albert Schweitzer** became famous—at about the same time that Leopold formulated a land ethic—for teaching reverence for life, and not just human life. Many non-western traditions also emphasize harmony and a respect for all living things. Such a context implies that a land ethic cannot easily be separated from age-old thinking on ethics in general. *See also* Land stewardship

Land Institute

Founded in 1976 by Wes and Dana Jackson, the Land Institute is both an independent agricultural research station and a school devoted to exploring and developing alternative agricultural practices. Located on the Smoky Hill River near Salina, Kansas, the Institute attempts—in Wes Jackson's words—to "make **nature** the measure" of human activities so that humans "meet the expectations of the land," rather than abusing the land for human needs. This requires a radical rethinking of traditional and modern farming methods. The aim of the Land Institute is to find "new roots for agriculture" by reexamining its traditional assumptions.

In traditional tillage farming, furrows are dug into the **topsoil** and seeds planted. This leaves precious topsoil exposed to **erosion** by wind and water. Topsoil loss can be minimized but not eliminated by **contour plowing**, the use of windbreaks, and other means. Although critical of traditional tillage agriculture, Jackson is even more critical of the methods and machinery of modern industrial agriculture, which in effect trades topsoil for high crop yields (roughly one bushel of topsoil is lost for every bushel of corn harvested). It also relies on plant monocultures—genetically uniform strains of corn, wheat, soybeans, and other crops. These crops are especially susceptible to disease and insect infestations and require extensive use of pesticides and herbicides which, in turn, kill useful creatures (for example, worms and birds), pollute streams and **groundwater**, and produce other destructive side effects. Although spectacularly successful in the short run, such an agriculture is both non-sustainable and self-defeating. Its supposed strengths—its productivity, its efficiency, its economies of scale—are also its weaknesses. Short-term gains in production do not, Jackson argues, justify the longer term depletion of topsoil, the diminution of genetic diversity, and such social side-effects as the disappearance of small family farms and the abandonment of rural communities.

If these trends are to be questioned—much less slowed or reversed—a practical, productive, and feasible alternative agriculture must be developed. To develop such a workable alternative is the aim of the Land Institute. The Jacksons and their associates are attempting to devise an alternative vision of agricultural possibilities. This begins with the important but oft-neglected truism that agriculture is not self-contained but is intertwined with and dependent on nature. The Institute explores the feasibility of alternative farming methods that might minimize or even eliminate the planting and harvesting of annual crops, turning instead to "herbaceous perennial seed-producing polycultures" that protect and bind topsoil. Food grains would be grown in pasture-like fields and intermingled with other plants that would replenish lost **nitrogen** and other nutrients, without relying on chemical fertilizers. Covered by a rooted living net of diverse plant life, the **soil** would at no time be exposed to erosion and would be aerated and rejuvenated by natural

means. And the farmer, in symbiotic partnership, would take nature as the measure of his methods and results.

The experiments at the Land Institute are intended to make this vision into a workable reality. It is as yet too early to tell exactly what these continuing experiments might yield. But the re-visioning of agriculture has already begun and continues at the Land Institute.

Land reform

Land reform is a social and political restructuring of the agricultural systems through redistribution of land. Successful land reform policies take into account the political, social, and economic structure of the area.

In agrarian societies, large landowners typically control the wealth and the distribution of food. Land reform policies in such societies allocate land to small landowners, to farm workers who own no land, to collective farm operations, or to state farm organizations. The exact nature of the allocation depends on the motivation of those initiating the changes. In areas where absentee ownership of farmland is common, land reform has become a popular method for returning the land to local ownership. Land reforms generally favor the family-farm concept, rather than absentee landholding.

Land reform is often undertaken as a means of achieving greater social equality, but it can also increase agricultural productivity and benefit the **environment**. A tenant farmer may have a more emotional and protective relation to the land he works, and he may be more likely to make agricultural decisions that benefit the **ecosystem**. Such a farmer might, for instance, opt for natural **pest** control. An absentee owner often does not have the same interest in **land stewardship**.

Land reform does have negative connotations and is often associated with the state collective farms under communism. Most proponents of land reform, however, do not consider these collective farms good examples, and they argue that successful land reform balances the factors of production so that the full agricultural capabilities of the land can be realized. Reforms should always be designed to increase the efficiency and economic viability of farming.

Land reform is usually more successful if it is enacted with agrarian reforms, which may include the use of agricultural extension agents, agricultural cooperatives, favorable labor legislation, and increased public services for farmers, such as health care and education. Without these measures land reform usually falls short of redistributing wealth and power, or fails to maintain or increase production. *See also* Agricultural pollution; Sustainable agriculture; Sustainable development

Land stewardship

Little has been written explicitly on the subject of land stewardship. Much of the literature that does exist is limited to a biblical or theological treatment of stewardship. However, literature on the related ideas of sustainability and the **land ethic** has expanded dramatically in recent years, and these concepts are at the heart of land stewardship.

Webster's and the *Oxford English Dictionary* both define a "steward" as an official in charge of a household, church, estate, or governmental unit, or one who makes social arrangements for various kinds of events; a manager or administrator. Similarly, stewardship is defined as doing the job of a steward or, in ecclesiastical terms, as "the responsible use of resources," meaning especially money, time and talents, "in the service of God."

Intrinsic in those restricted definitions is the idea of responsible caretakers, of persons who take good care of the resources in their charge, including **natural resources**. "Caretaking" universally includes caring for the material resources on which people depend, and by extension, the land or **environment** from which those resources are extracted. Any concept of steward or stewardship must include the notion of ensuring the essentials of life, all of which derive from the land.

While there are few works written specifically on land stewardship, the concept is embedded implicitly and explicitly in the writings of many articulate environmentalists. For example, Wendell Berry, a poet and essayist, is one of the foremost contemporary spokespersons for stewardship of the land. In his books, *Farming: A Handbook* (1970), *The Unsettling of America* (1977), *The Gift of Good Land* (1981), and *Home Economics* (1987), Berry shares his wisdom on caring for the land and the necessity of stewardship. He finds a mandate for good stewardship in religious traditions, includ-

ing Judaism and Christianity: "The divine mandate to use the world justly and charitably, then, defines every person's moral predicament as that of a steward." Berry, however, does not leave stewardship to divine intervention. He describes stewardship as "hopeless and meaningless unless it involves long-term courage, perseverance, devotion, and skill" on the part of individuals, and not just farmers. He suggests that when we lost the skill to use the land properly, we lost stewardship.

However, Berry does not limit his notion of stewardship to a biblical or religious one. He lays down seven rules of land stewardship—rules of "living right." These are:

- using the land will lead to ruin of the land unless it "is properly cared for;"
- if people do not know the land intimately, they cannot care for it properly;
- motivation to care for the land cannot be provided by "general principles or by incentives that are merely economic;"
- motivation to care for the land, to live with it, stems from an interest in that land that "is direct, dependable, and permanent;"
- motivation to care for the land stems from an expectation that people will spend their entire lives on the land, and even more so if they expect their children and grandchildren to also spend their entire lives on that same land;
- the ability to live carefully on the land is limited; owning too much acreage, for example, decreases the quality of attention needed to care for the land;
- a nation will destroy its land and therefore itself if it does not foster rural households and communities that maintain people on the land as outlined in the first six rules.

Stewardship implies at the very least then, an attempt to reconnect to a piece of land. Reconnecting means getting to know that land as intimately as possible. This does not necessarily imply ownership, although enlightened ownership is at the heart of land stewardship. People who own land have some control of it, and effective stewardship requires control, if only in the sense of enough power to prevent abuse. But, ownership obviously does not guarantee stewardship—great and widespread abuses of land are perpetrated by owners. Absentee ownership, for example, often means a lack of connection, a lack of knowledge, and a lack of caring. And public ownership too often means non-ownership, leading to the "Tragedy of the Commons." Land ownership patterns are critical to stewardship, but no one type of ownership guarantees good stewardship.

Berry argues that true land stewardship usually begins with one small piece of land, used or controlled or owned by an individual who lives on that land. Stewardship, however, extends beyond any one particular piece of land. It implies knowledge, and caring for, the entire system of which that land is a part, a knowledge of a land's context as well as its content. It also requires understanding the connections between landowners or land users and the larger communities of which they are a part. This means that stewardship depends on interconnected systems of **ecology** and economics, of politics and science, of sociology and planning. The web of life that exists interdependent with a piece of land mandates attention to a complex matrix of connections. Stewardship means keeping the web intact and functional, or at least doing so on enough land over a long-enough period of time to sustain the populations dependent on that land.

Berry and many other critics of contemporary land-use patterns and policies claim that little attention is being paid to maintaining the complex communities on which sustenance, human and otherwise, depends. Until holistic, ecological knowledge becomes more of a basis for economic and political decision-making, they assert, stewardship of the critical land-base will not become the norm. *See also* Environmental ethics; Holistic approach; Land use; Sustainable agriculture; Sustainable biosphere; Sustainable development

Land Stewardship Project

The **Land Stewardship** Project (LSP) is a nonprofit organization based in Minnesota and committed to promoting an ethic of environmental and agricultural stewardship. The group believes that the natural **environment** is not an exploitable resource but a gift given to each generation for safekeeping. To preserve and pass on this gift to **future generations**, for the LSP, is both a moral and a practical imperative.

Founded in 1982, the LSP is an alliance of farmers and city-dwellers dedicated both to preserving the small family farm and practicing **sustainable agriculture**. Like Wendell Berry and **Wes Jackson** (with whom they are affiliated), the LSP is critical of conventional agricultural

practices that emphasize plant monocultures, large acreage, intensive tillage, extensive use of herbicides and pesticides, and the economies of scale that these practices make possible. The group believes that agriculture conducted on such an industrial scale is bound to be destructive not only of the natural environment but of family farms and rural communities as well. The LSP accordingly advocates the sort of smaller scale agriculture that, in Berry's words, "depletes neither **soil**, nor people, nor communities."

The LSP sponsors legislative initiatives to save farmland and **wildlife habitat**, to limit **urban sprawl** and protect family farms, and to promote sustainable agricultural practices. It supports educational and outreach programs to inform farmers, consumers, and citizens about agricultural and environmental issues. The LSP also publishes a quarterly *Land Stewardship Letter* and distributes video tapes about sustainable agriculture and other environmental concerns.

Land trusts

A land trust is a private, legally incorporated, nonprofit organization that works with property owners to protect open land through direct, voluntary land transactions. Land trusts come in many varieties, but their intent is consistent. Land trusts are developed for the purpose of holding land against a development plan until the public interest can be ascertained and served. Some land trusts hold land open until public entities can purchase it. Some land trusts purchase land and manage it for the common good. In some cases land trusts buy development rights to preserve the land area for **future generations** while leaving the current use in the hands of private interests with written documentation as to how the land can be used. This same technique can be used to adjust **land use** so that some part of a parcel is preserved while another part of the same parcel can be developed, all based on land sensitivity.

There is a hierarchy of land trusts. Some trusts protect areas as small as neighborhoods, forming to address one land use issue after which they disband. More often, land trusts are local in nature but have a global perspective with regard to their goals for future land protection. The big national trusts are names that we all recognize such as the Conservation Fund, **The Nature Conservancy**, the **American Farmland Trust**, and the Trust for **Public Land**. The Land Trust Alliance coordinates the activities of many land trusts. Currently, there are over 1,200 local and regional land trusts in the United States. Some of these trusts form as a direct response to citizen concerns about the loss of open space. Most land trusts evolve out of citizen's concerns over the future of their state, town, and neighborhood. Many are preceded by failures on the part of local governments to respond to stewardship mandates by the voters.

Land trusts work because they are built by concerned citizens and funded by private donations with the express purpose of securing the sustainability of an acceptable quality of life. Also, land trusts are effective because they purchase land (or development rights) from local people for local needs. Transactions are often carried out over a kitchen table with neighbors discussing priorities. In some cases the trust's board of directors might be engaged in helping a citizen to draw up a will leaving farmland or potential **recreation** land to the community. This home rule concept is the backbone of the land trust movement. Additionally, land trusts gain strength from public/private partnerships that emerge as a result of shared objectives with governmental agencies. If the work of the land trust is successful, part of the outcome is an enhanced ability to cooperate with local government agencies. Agencies learn to trust the land trust staff and begin to rely on the special expertise that grows within a land trust organization. In some cases the land trust gains both opportunities and resources as a result of its partnership with governmental agencies. This public/private partnership benefits citizens as projects come together and land use options are retained for current and future generations.

Flexibility is an important and essential quality of a land trust that enables it to be creative. Land trusts can have revolving accounts, or lines of credit, from banks that allow them to move quickly to acquire land. Compensation to landowners who agree to work with the trust may come in the form of extended land use for the ex-owner, land trades, tax compensation, and other compensation packages. Often some mix of protection and compensation packages will be created that a governmental agency simply does not have the ability to implement. A land trust's flexibility is its most important attribute. Where a land trust can negotiate land acquisition based on a discussion among the board members, a governmental agency would go through months or even years of red tape before an offer to buy land for the public domain could be made. This quality of land trusts is one reason why many governmental agencies have built relationships with land trusts in order to protect land that the agency deems sensitive and important.

There are some limiting factors constraining what land trusts can do. For the more localized trusts, limited volunteer staff and extremely limited budgets cause fund raising to

become a time-consuming activity. Staff turnover can be frequent so that a knowledge base is difficult to maintain. In some circumstances influential volunteers can capture a land trust organization and follow their own agenda rather than letting the agenda be set by affected stakeholders.

Training is needed for those committed to working within the legal structure of land trusts. The national Trust for Public Lands has established training opportunities to better prepare local land trust staff for the complex negotiations that are needed to protect public lands. Staff that work with local citizenry to protect local needs must be aware of the costs and benefits of land preservation mechanisms. Lease purchase agreements, limited partnerships, and fee simple transactions all require knowledge of real estate law. Operating within enterprise zones and working with economic development corporations requires knowledge of state and federal programs that provide money for projects on the urban fringe. In some cases urban renewal work reveals open space within the urban core that can be preserved for community gardens or parks if that land can be secured using HUD funds or other government financing mechanisms. A relatively new source of funding for land acquisition is mitigation funds. These funds are usually generated as a result of settlements with industry or governmental agencies as compensation for negative land impacts. Distinguishing among financing mechanisms requires specialized knowledge that land trust staff need to have available within their ranks in order to move quickly to preserve open space and enhance the quality of life for urban dwellers. On the other hand some land trusts in rural areas are interested in conserving farmlands using preserves that allow farmers to continue to farm while protecting the rural character of the countryside. Like their urban counterparts, these farmland preserve programs are complex, and if they are to be effective the trust needs to employ its solid knowledge of economic trends and resources.

The work that land trusts do is varied. In some cases a land trust incorporates as a result of a local threat, such as a pipeline or railway coming through an area. In some cases a trust forms to counter an undesirable land use such as a **landfill** or a **low-level radioactive waste** storage facility. In other instances, a land trust comes together to take advantage of a unique opportunity, such as a family wanting to sell some pristine forest close to town or an industry deciding to relocate leaving a lovely waterfront location with promise as a riverfront recreation area. It is rare that a land trust forms without a focused need. However, after the initial project is completed, its success breeds self-confidence in those who worked on the project and new opportunities or challenges may sustain the goals of the fledgling organization.

There are many examples of land trusts and the few highlighted here may help to enhance understanding of the value of land trust activities and to offer guidance to local groups wanting to preserve land. One outstanding example of land trust activity is the Rails to Trails program in Michigan. Under this program, abandoned railroad right of ways are preserved to create green belts for recreation use through agreements with the railroad companies. The Trust for Public Lands (TPL) has assisted many local land trusts to implement a wide variety of land acquisition projects. One such complex agreement took place in Tucson, Arizona. In this case, the Tucson city government wanted to acquire seven parcels of land that totaled 40 acres (164 ha). For financial reasons the city was not able to acquire the land. At that point the Trust for Public Land was asked to become a private nonprofit partner and to work with the city to acquire the land. TPL used its creative expertise to help each of the landowners make mutually beneficial arrangements with the city so that a large urban park could become a reality. In some cases the TPL offered a life tenancy to the current owners in exchange for a reduced land price. In another case they offered a five-year tenancy and a job as caretaker, in exchange for a reduced purchase price. As the community worked on the future of the park, another landowner who owned a contiguous parcel stepped forward with an offer to sell. Each of these transactions was successful because the land trust was flexible, considerate of the land owners and up front about the goals of their work, and responsive to their public partner, the city government.

Our current land trust effort in the United States has affected the way we protect our sensitive lands, reclaim damaged lands, and respond to local needs. Land trusts conserve land, guide future planning, educate local citizens and government agencies to a new way of doing business, and do it all with a minimum amount of confrontation and legal interaction. These private, non-profit organizations have stepped in and filled a **niche** in the environmental conservation movement started in the 1970s and have gotten results through a system of cooperative and well-informed action.

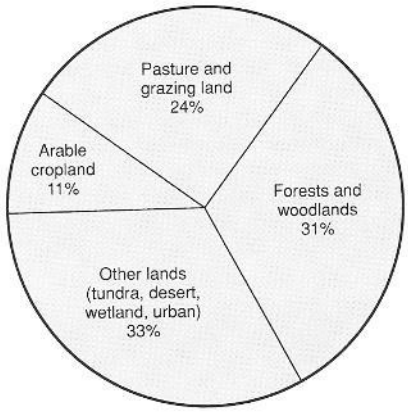
Land use

Land is any part of the earth's surface that can be owned as property. Land comprises a particular segment of the earth's crust and can be defined in specific terms. The location of the land is extremely important in determining land use and land value.



Land is limited in supply, and, as our population increases, we have less land to support each person. Land nurtures the plants and animals that provide our food and shelter. It is the **watershed** or **reservoir** for our water supply. Land provides the minerals we utilize, the space on which we build our homes, and the site of many recreational activities. Land is also the depository for much of the waste created by modern society. The growth of human population only provides a partial explanation for the increased pressure on land resources. Economic development and a rise in the standard of living have brought about more demands for the products of the land. This demand now threatens to erode the land resource.

We are terrestrial in our activities and as our needs have diversified, so has land use. Conflicts among the competing land uses have created the need for land-use planning. Previous generations have used and misused the land as though the supply was inexhaustible. Today, goals and decisions about land use must take into account and link information from the physical and biological sciences with the current social values and political realities.

Land characteristics and ownership provide a basis for the many uses of land. Some land uses are classified as irreversible, for example, when the application of a particular land use changes the original character of the land to such a extent that reversal to its former use is impracticable. Reversible land uses do not change the **soil** cover or landform, and the land manager has many options when overseeing reversible land uses.

A framework for land-use planning requires the recognition that plans, policies, and programs must consider physical and biological, economical, and institutional factors. The physical framework of land focuses on the inanimate resources of soil, rocks and geological features, water, air, sunlight, and **climate**. The biological framework involves living things such as plants and animals. A key feature of the physical and biological framework is the need to maintain healthy ecological relationships. The land can support many human activities, but there are limits. Once the resources are brought to these limits, they can be destroyed and replacing them will be difficult.

The economic framework for land use requires that operators of land be provided sufficient returns to cover the cost of production. Surpluses of returns above costs must be realized by those who make the production decisions and by those who bear the production costs. The economic framework provides the incentive to use the land in a way that is economically feasible. The institutional framework requires that programs and plans be acceptable within the working rules of society. Plans must also have the support of current governments. A basic concept of land use is the *right of land*—who has the right to decide the use of a given tract of land. Legal decisions have provided the framework for land resource protection.

World land use. (McGraw-Hill Inc. Reproduced by permission.)

Attitudes play an important role in influencing land use decisions, and changes in attitudes will often bring changes in our institutional framework. Recent trends in land use in the United States show that substantial areas have shifted to urban and **transportation** uses, state and national parks, and **wildlife** refuges since 1950. The use of land has become one of our most serious environmental concerns. Today's land use decisions will determine the quality of our future life styles and **environment**. The land use planning process is one of the most complex and least understood domestic concerns facing the nation. Additional changes in the institutional framework governing land use are necessary to allow society to protect the most limited resource on the planet—the land we live on.

Landfill

Surface water, oceans and landfills are traditionally the main repositories for society's solid and **hazardous waste**. Landfills are located in excavated areas such as sand and gravel pits or in valleys that are near waste generators. They have been cited as sources of surface and **groundwater** contamination and are believed to pose a significant health risk to humans, domestic animals, and **wildlife**. Despite these adverse effects and the attendant publicity, landfills are likely to remain a major waste disposal option for the immediate future.

Among the reasons that landfills remain a popular alternative are their simplicity and versatility. For example, they are not sensitive to the shape, size, or weight of a particular waste material. Since they are constructed of **soil**, they are rarely affected by the chemical composition of a particular waste component or by any collective incompatibility of co-mingled wastes. By comparison, **composting** and **incineration** require uniformity in the form and chemical properties of the waste for efficient operation. Landfills also have been a relatively inexpensive disposal option, but this situation is rapidly changing. Shipping costs, rising land prices, and new landfill construction and maintenance requirements contribute to increasing costs.

About 57% of the **solid waste** generated in the United States still is dumped in landfills. In a sanitary landfill, refuse is compacted each day and covered with a layer of dirt. This procedure minimizes odor and litter, and discourages insect and rodent populations that may spread disease. Although this method does help control some of the **pollution** generated by the landfill, the fill dirt also occupies up to 20 percent of the landfill space, reducing its waste-holding capacity. Sanitary landfills traditionally have not been enclosed in a waterproof lining to prevent **leaching** of **chemicals** into groundwater, and many cases of **groundwater pollution** have been traced to landfills.

Historically landfills were placed in a particular location more for convenience of access than for any environmental or geological reason. Now more care is taken in the siting of new landfills. For example, sites located on faulted or highly **permeable** rock are passed over in favor of sites with a less-permeable foundation. Rivers, lakes, floodplains, and groundwater recharge zones are also avoided. It is believed that the care taken in the initial siting of a landfill will reduce the necessity for future clean-up and site **rehabilitation**. Due to these and other factors, it is becoming increasingly difficult to find suitable locations for new landfills.

A secure landfill. (McGraw-Hill Inc. Reproduced by permission.)

Easily accessible open space is becoming scarce and many communities are unwilling to accept the siting of a landfill within their boundaries. Many major cities have already exhausted their landfill capacity and must export their trash, at significant expense, to other communities or even to other states and countries.

Although a number of significant environmental issues are associated with the disposal of solid waste in landfills, the disposal of hazardous waste in landfills raises even greater environmental concerns. A number of urban areas contain hazardous waste landfills. **Love Canal** is, perhaps, the most notorious example of the hazards associated with these landfills. This Niagara Falls, New York neighborhood was built over a dump containing 20,000 metric tons of toxic chemical waste. Increased levels of **cancer**, miscarriages, and **birth defects** among those living in Love Canal led to the eventual evacuation of many residents. The events at Love Canal were also a major impetus behind the passage of the Comprehensive Environmental Response, Compensation and Liability Act in 1980, designed to clean up such sites. The U. S. **Environmental Protection Agency** estimates that there may be as many as 2,000 hazardous waste disposal sites in this country that pose a significant threat to human health or the **environment**.

Love Canal is only one example of the environmental consequences that can result from disposing of hazardous waste in landfills. However, techniques now exist to create secure landfills that are an acceptable disposal option for hazardous waste in many cases. The bottom and sides of a secure landfill contain a cushion of recompacted clay that is flexible and resistant to cracking if the ground shifts. This clay layer is impermeable to groundwater and safely contains the waste. A layer of gravel containing a grid of perforated drain pipes is laid over the clay. These pipes collect any

seepage that escapes from the waste stored in the landfill. Over the gravel bed a thick polyethylene liner is positioned. A layer of soil or sand covers and cushions this plastic liner, and the wastes, packed in drums, are placed on top of this layer.

When the secure landfill reaches capacity it is capped by a cover of clay, plastic and soil, much like the bottom layers. Vegetation in planted to stabilize the surface and make the site more attractive. Sump pumps collect any fluids that filter through the landfill either from rainwater or from waste leakage. This liquid is purified before it is released. Monitoring **wells** around the site ensure that the groundwater does not become contaminated. In some areas where the **water table** is particularly high, above-ground storage may be constructed using similar techniques. Although such facilities are more conspicuous, they have the advantage of being easier to monitor for leakage.

Although technical solutions have been found to many of the problems associated with secure landfills, several nontechnical issues remain. One of these issues concerns the **transportation** of hazardous waste to the site. Some states do not allow hazardous waste to be shipped across their territory because they are worried about the possibility of accidental spills. If hazardous waste disposal is concentrated in only a few sites, then a few major transportation routes will carry large volumes of this material. Citizen opposition to hazardous waste landfills is another issue. Given the past record of corporate and governmental irresponsibility in dealing with hazardous waste, it is not surprising that community residents greet proposals for new landfills with the NIMBY (**Not In My BackYard**) response. However, the waste must go somewhere. These and other issues must be resolved if secure landfills are to be a viable long-term solution to hazardous waste disposal. *See also* Groundwater monitoring; International trade in toxic waste; Storage and transportation of hazardous materials

Landscape ecology

Landscape **ecology** is an interdisciplinary field that emerged from several intellectual traditions in Europe and North America. An identifiable landscape ecology started in central Europe in the 1960s and in North America in the late 1970s and early 1980s. It became more visible with the establishment, in 1982, of the International Association of Landscape Ecology, with the publication of a major text in the field, *Landscape Ecology*, by Richard Forman and Michel Godron in 1984, and with the publication of the first issue of the association's journal, *Landscape Ecology* in 1987.

The phrase 'landscape ecology' was first used in 1939 by the German geographer, Carl Troll. He suggested that the "concept of landscape ecology is born from a marriage of two scientific outlooks, the one geographical (landscape), the other biological (ecology)." Troll coined the term landscape ecology to denote "the analysis of a physico-biological complex of interrelations, which govern the different area units of a region." He believed that "landscape ecology...must not be confined to the large scale analysis of natural regions. Ecological factors are also involved in problems of population, society, rural settlement, **land use**, transport, etc."

Landscape has long been a unit of analysis and a conceptual centerpiece of geography, with scholars such as Carl Sauer and J. B. Jackson adept at "reading the landscape," including both the natural landscape of landforms and vegetation, and the cultural landscape as marked by human actions and as perceived by human minds.

Zev Naveh has been working on his own version of landscape ecology in Israel since the early 1970s. Like Troll, Naveh includes humans in his conception, in fact enlarges landscape ecology to a global human **ecosystem** science, sort of a "bio-cybernetic systems approach to the landscape and the study of its use by [humans]." He sees landscape ecology first as a **holistic approach** to biosystems theory, the centerpiece being "recognition of the total human ecosystem as the highest level of integration," and, second, as playing a central role in cultural **evolution** and as a "basis for interdisciplinary, task-oriented, environmental education."

Landscape architecture is also to some extent landscape ecology, since landscape architects design complete vistas, from their beginnings and at various scales. This concern with designing and creating complete landscapes from bare ground can certainly be considered ecological, as it includes creating or adapting local land forms, planting appropriate

vegetation, and designing and building various kinds of 'furniture' and other artifacts on site. The British Landscape Institute and the British Ecological Society held a joint meeting in 1983, recognizing "that the time for ecology to be harnessed for the service of landscape design has arrived." The meeting produced the twenty-fourth symposium of the British Ecological Society titled *Ecology and Design in Landscape*.

Landscape planning can also to some degree be considered landscape ecology, especially in the ecological approach to landscape planning developed by Ian McHarg and his students and colleagues, and the LANDEP, or Landscape Ecological Planning, approach designed by Ladislav Miklos and Milan Ruzicka. Both of these ecological planning approaches are complex syntheses of spatial patterns, ecological processes, and human needs and wants.

Building on all of these traditions, yet slowly finding its own identity, landscape ecology is considered by some as a sub-domain of biological ecology and by others as a discipline in its own right. In Europe, landscape ecology continues to be an extension of the geographical tradition that is preoccupied with human-landscape interactions. In North America, landscape ecology has emerged as a branch of biological ecology, more concerned with landscapes as clusters of interrelated natural ecosystems. The European form of landscape ecology is applied to land and resource **conservation**, while in North America it focuses on fundamental questions of spatial pattern and exchange. Both traditions can address major environmental problems, especially the **extinction** of **species** and the maintenance of biological diversity.

The term landscape, despite the varied traditions and emerging disciplines described above, remains somewhat indeterminate, depending on the criteria set by individual researchers to establish boundaries. Some consensus exists on its general definition in the new landscape ecology, as described in the composite form attempted here: a terrestrial landscape is miles- or kilometers-wide in area; it contains a cluster of interacting ecosystems repeated in somewhat similar form; and it is a heterogeneous mosaic of interconnected land forms, vegetation types, and land uses. As Risser and his colleagues emphasize, this interdisciplinary area focuses explicitly on spatial patterns: "Specifically, landscape ecology considers the development and dynamics of spatial hetereogeneity, spatial and temporal interactions and exchanges across heterogeneous landscapes, influences of spatial heterogeneity on biotic and abiotic processes, and management of spatial heterogeneity." Instead of trying to identify homogeneous ecosystems, landscape ecology focuses particularly on the heterogeneous patches and mosaics created by human disruption of natural systems, by the intermixing of cultural and natural landscape patterns. The real rationale for a landscape ecology perhaps should be this acknowledgment of the heterogeneity of contemporary landscape patterns, and the need to deal with the patchwork mosaics and intricate matrices that result from long-term human disturbance, modification, and utilization of natural systems.

Typical questions asked by landscape ecologists include these formulated by Risser and his colleagues: "What formative processes, both historical and present, are responsible for the existing pattern in a landscape?" "How are fluxes of organisms, of material, and of energy related to landscape heterogeneity?" "How does landscape heterogeneity affect the spread of disturbances?" While the first question is similar to ones long asked in geography, the other two are questions traditional to ecology, but distinguished here by the focus on heterogeneity.

Richard Forman, a prominent figure in the evolving field of landscape ecology, thinks the field has matured enough for general principles to have emerged; not ecological laws as such, but principles backed by enough evidence and examples to be true for 95 percent of landscape analyses. His 12 principles are organized by four categories: landscapes and regions; patches and corridors; mosaics; and applications. The principles outline expected or desirable spatial patterns and relationships, and how those patterns and relationships affect system functions and flows, organismic movements and extinctions, resource protection, and optimal environmental conditions. Forman claims the principles "should be applicable for any environmental or societal land-use objective," and that they are useful in more effectively "growing wood, protecting species, locating houses, protecting **soil**, enhancing game, protecting **water resources**, providing **recreation**, locating roads, and creating sustainable environments."

Perhaps Andre Corboz provided the best description when he wrote of "the land as palimpsest:" landscape ecology recognizes that humans have written large on the land, and that behind the current writing visible to the eye, there is earlier writing as well, which also tells us about the patterns we see. Landscape ecology also deals with gaps in the text and tries to write a more complete accounting of the landscapes in which we live and on which we all depend.

Landslide

A general term for the discrete downslope movement of rock and **soil** masses under gravitational influence along a failure zone. The term "landslide" can refer to the resulting land form, as well as to the process of movement. Many types of landslides occur, and they are classified by several schemes, according to a variety of criteria. Landslides are categorized most commonly on basis of geometric form, but also by size, shape, rate of movement, and water content or fluidity. Translational, or planar, failures, such as debris avalanches and earth flows, slide along a fairly straight failure surface which runs approximately parallel to the ground surface. Rotational failures, such as rotational slumps, slide along a spoon shaped failure surface, leaving a hummocky appearance on the landscape. Rotational slumps commonly transform into earthflows as they continue down slope. Landslides are usually triggered by heavy rain or melting snow, but major earthquakes can also cause landslides.

Land-use control

Land-use control is a relatively new concept. For most of human history, it was assumed that people could do whatever they wished with their own property. However, societies have usually recognized that the way an individual uses private property can sometimes have harmful affects on neighbors.

Land-use planning has reached a new level of sophistication in developed countries over the last century. One of the first restrictions on **land use** in the United States, for example, was a 1916 New York City law limiting the size of skyscrapers because of the shadows they might cast on adjacent property. Within a decade, the federal government began to act aggressively on land control measures. It passed the **Mineral Leasing Act** of 1920 in an attempt to control the exploitation of oil, **natural gas**, phosphate, and potash. It adopted the Standard State Zoning Act of 1922 and the Standard City Planning Enabling Act of 1928 to promote the concept of zoning at state and local levels. Since the 1920s, every state and most cities have adopted zoning laws modeled on these two federal acts.

Often detailed, exhaustive, and complex zoning regulations now control the way land is used in nearly every governmental unit. They specify, for example, whether land can be used for single-dwelling construction, multiple-dwelling construction, farming, industrial (heavy or light) development, commercial use, **recreation** or some other purpose. Requests to use land for purposes other than that for which it is zoned requires a variance or conditional use permit, a process that is often long, tedious, and confrontational.

Many types of land require special types of zoning. For example, coastal areas are environmentally vulnerable to storms, high tides, **flooding**, and strong winds. The federal government passed laws in 1972 and 1980, the National Coastal Zone Management Acts, to help states deal with the special problem of protecting coastal areas. Although initially slow to make use of these laws, states are becoming more aggressive about restricting the kinds of construction permitted along seashore areas.

Areas with special scenic, historic, or recreational value have long been protected in the United States. The nation's first **national park**, **Yellowstone National Park**, was created in 1872. Not until 44 years later, however, was the **National Park Service** created to administer Yellowstone and other parks established since 1872. Today, the National Park Service and other governmental agencies are responsible for a wide variety of national areas such as forests, wild and scenic rivers, historic monuments, trails, battlefields, memorials, seashores and lakeshores, parkways, recreational areas, and other areas of special value.

Land-use control does not necessarily restrict usage. Individuals and organizations can be encouraged to use land in certain desirable ways. An enterprise zone, for example, is a specifically designated area in which certain types of business activities are encouraged. The tax rate might be reduced for businesses locating in the area or the government might relax certain regulations there.

Successful land-use control can result in new towns or planned communities, designed and built from the ground up to meet certain pre-determined land-use objectives. One of the most famous examples of a planned community is Brasilia, the capital of Brazil. The site for a new capital—an undeveloped region of the country—was selected and a totally new city was built in the 1950s. The federal government moved to the new city in 1960, and it now has a population of more than 1.5 million. *See also* Bureau of Land Management; Riparian rights

Latency

Latency refers to the period of time it takes for a disease to manifest itself within the human body. It is the state of seeming inactivity that occurs between the instant of stimulation or initiating event and the beginning of response. The latency period differs dramatically for each stimulation and as a result, each disease has its unique time period before symptoms occur.

When pathogens gain entry into a potential host, the body may fail to maintain adequate immunity and thus permits progressive viral or bacterial multiplication. This time lapse is also known as the incubation period. Each disease has definite, characteristic limits for a given host. During the incubation period, dissemination of the **pathogen** takes place and leads to the inoculation of a preferred or target organ. Proliferation of the pathogen, either in a target organ or throughout the body, then creates an infectious disease.

Botulism, tetanus, gonorrhea, diphtheria, staphylococcal and streptococcal disease, pneumonia, and tuberculosis are among the diseases that take varied periods of time before the symptoms are evident. In the case of the childhood diseases—measles, mumps, and chicken pox—the incubation period is 14–21 days.

In the case of **cancer**, the latency period for a small group of transformed cells to result in a tumor large enough to be detected is usually 10–20 years. One theory postulates that every cancer begins with a single cell or small group of cells. The cells are transformed and begin to divide. Twenty years of cell division ultimately results in a detectible tumor. It is theorized that very low doses of a **carcinogen** could be sufficient to transform one cell into a cancerous tumor.

In the case of **AIDS**, an eight- to eleven-year latency period passes before the symptoms appear in adults. The length of this latency period depends upon the strength of the person's immune system. If a person suspects he or she has been infected, early blood tests showing HIV antibodies or antigens can indicate the infection within three months of the stimulation. The three-month period before the appearance of HIV antibodies or antigens is called the "window period."

In many cases, doctors may fail to diagnose the disease at first, since AIDS symptoms are so general they may be confused with the symptoms of other, similar diseases. Childhood AIDS symptoms appear more quickly since young children have immune systems that are less fully developed.

[*Liane Clorfene Casten*]

Lawn treatment

Lawn treatment in the form of pesticides and inorganic fertilizers poses a substantial threat to the **environment**. Homeowners in the United States use approximately three times more pesticides per acre than the average farmer, adding up to some 136 million pounds (61.7 kg)annually. Home lawns occupy more acreage in the United States than any agricultural crop, and a majority of the **wildlife pesticide** poisonings tracked by the **Environmental Protection Agency** (EPA) annually are attributed to **chemicals** used in lawn care. The use of grass **fertilizer** is also problematic when it runs off into nearby waterways. Lawn grass in almost all climates in the United States requires watering in the summer, accounting for some 40 to 60 percent of the average homeowner's water use annually. Much of the water sprinkled on lawns is lost as **runoff**. When this runoff carries fertilizer, it can cause excess growth of algae in downstream waterways, clogging the surface of the water and depleting the water of oxygen for other plants and animals. Herbicides and pesticides are also carried into downstream water, and some of these are toxic to fish, birds, and other wildlife.

Turf grass lawns are ubiquitous in all parts of the United States, regardless of the local **climate**. From Alaska to Arizona to Maine, homeowners surround their houses with grassy lawns, ideally clipped short, brilliantly green, and free of weeds. In almost all cases, the grass used is a hybrid of several **species** of grass from Northern Europe. These grasses thrive in cool, moist summers. In general, the United States experiences hotter, dryer summers than Northern Europe. Moving from east to west across the country, the climate becomes less and less like that the common turf grass evolved in. The ideal American lawn is based primarily on English landscaping principals, and it does not look like an English lawn unless it is heavily supported with water.

The prevalence of lawns is a relatively recent phenomenon in the United States, dating to the late nineteenth century. When European settlers first came to this country, they found indigenous grasses that were not as nutritious for livestock and died under the trampling feet of sheep and cows. Settlers replaced native grasses with English and European grasses as fodder for grazing animals. In the late eighteenth century, American landowners began surrounding their estates with lawn grass, a style made popular

earlier in England. The English lawn fad was fueled by eighteenth century landscaper Lancelot "Capability" Brown, who removed whole villages and stands of mature trees and used sunken fences to achieve uninterrupted sweeps of green parkland. Both in England and the United States, such lawns and parks were mowed by hand, requiring many laborers, or they were kept cropped by sheep or even deer. Small landowners meanwhile used the land in front of their houses differently. The yard might be of stamped earth, which could be kept neatly swept, or it may have been devoted to a small garden, usually enclosed behind a fence. The trend for houses set back from the street behind a stretch of unfenced lawn took hold in the mid-nineteenth century with the growth of suburbs. Frederick Law Olmsted, the designer of New York City's Central Park, was a notable suburban planner, and he fueled the vision of the English manor for the suburban home. The unfenced lawns were supposed to flow from house to house, creating a common park for the suburb's residents. These lawns became easier to maintain with the invention of the lawn mower. This machine debuted in England as early as 1830, but became popular in the United States after the Civil War. The first patent for a lawn sprinkler was granted in the United States in 1871. These developments made it possible for middle class home owners to maintain lush lawns themselves.

Chemicals for lawn treatment came into common use after World War II. Herbicides such as **2,4-D** were used against broadleaf weeds. The now-banned DDT was used against insect pests. Homeowners had previously fertilized their lawns with commercially available organic formulations like dried manure, but after World War II inorganic, chemical-based fertilizers became popular for both agriculture and lawns and gardens. Lawn care companies such as Chemlawn and Lawn Doctor originated in the 1960s, an era when homeowners were confronted with a bewildering array of chemicals deemed essential to a healthy lawn. Rachel Carson's 1962 book *Silent Spring* raised an alarm about the prevalence of lawn chemicals and their environmental costs. Carson explained how the insecticide DDT builds up in the food chain, passing from insects and worms to fish and small birds that feed on them, ultimately endangering large predators like the eagle. DDT was banned in 1972, and some lawn care chemicals were restricted. Nevertheless, the lawn care industry continued to prosper, offering services such as combined seeding, **herbicide**, and fertilizer at several intervals throughout the growing season. Lawn care had grown to a $25 billion industry in the United States by the 1990s. Even as the perils of particular lawn chemicals became clearer, it was difficult for homeowners to give them up. **Statistics** from the United States National **Cancer** Institute show that the incidence of childhood **leukemia** is 6.5% greater in familes that use lawn pesticides than in those who do not. In addition, 32 of the 34 most widely used lawn care pesticides have not been tested for health and environmental issues. Because some species of lawn grasses grow poorly in some areas of the United States, it does not thrive without extra water and fertilizer. It is vulnerable to insect pests, which can be controlled with pesticides, and if a weed-free lawn is the aim, herbicides are less labor-intensive than digging out dandelions one by one.

Some common pesticides used on lawns are acephate, bendiocarb, and **diazinon**. Acephate is an **organophosphate** insecticide which works by damaging the insect's nervous system. Bendiocarb is called a carbamate insecticide, sold under several brand names, which works in the same way. Both were first developed in the 1940s. These will kill many insects, not only pests such as leafminers, thrips, and cinch bugs, but also beneficial insects, such as bees. Bendiocarb is also toxic to earthworms, a major food source for some birds. Birds too can die from direct exposure to bendiocarb, as can fish. Both these chemicals can persist in the **soil** for weeks. Diazinon is another common pesticide used by homeowners on lawns and gardens. It is toxic to humans, birds, and other wildlife, and it has been banned for use on **golf courses** and turf farms. Nevertheless, homeowners may use it to kill **pest** insects such as **fire ants**. Harmful levels of diazinon and were found in metropolitan storm water systems in California in the early 1990s, leached there from orchard run-off. Diazinon is responsible for about half of all reported wildlife poisonings involving lawn and garden chemicals.

Common lawn and garden herbicides appear to be much less toxic to humans and animals than pesticides. The herbicide 2,4-D, one of the earliest herbicides used in this country, can cause skin and eye irritation to people who apply it, and it is somewhat toxic to birds. It can be toxic to fish in some formulations. Although contamination with 2,4-D has been found in some urban waterways, it has only been in trace amounts not thought to be harmful to humans. Glyphosate is another common herbicide, sold under several brand names, including the well-known Roundup. It is considered non-toxic to humans and other animals. Unike 2,4-D, which kills broadleaf plants, glyphosate is a broad spectrum herbicide used to control control a great variety of annual, biennial, and perennial grasses, sedges, broad leafed weeds and woody shrubs.

Common lawn and garden fertilizers are generally not toxic unless ingested in sufficient doses, yet they can have serious environmental effects. Run-off from lawns can carry fertilizer into nearby waterways. The **nitrogen** and **phosphorus** in the fertilizer stimulates plant growth, principally algae and microscopic plants. These tiny plants bloom, die, and decay. Bacteria that feed off plant decay then also undergo a surge in population. The overabundant bacteria con-

sume oxygen, leading to oxygen-depleted water. This condition is called hypoxia. In some areas, fertilized run-off from lawns is as big a problem as run-off from agricultural fields. Lawn fertilizer is thought to be a major culprit in **pollution** of the **Everglades** in Florida. In 2001 the Minnesota legislature debated a bill to limit homeowners' use of phosphorus in fertilizers because of problems with algae blooms on the state's lakes.

There are several viable alternatives to the use of chemicals for lawn care. Lawn care companies often recommend multiple applications of pesticides, herbicides, and fertilizers, but an individual lawn may need such treatment on a reduced schedule. Some insects such as thrips and mites are suceptible to insecticidal soaps and oils, which are not long-lasting in the environment. These could be used in place of diazinon, acephate and other pesticides. Weeds can be pulled by hand, or left alone. Homeowners can have their lawn evaluated and their soil tested to determine how much fertilizer is needed. Slow-release fertilizers or organic fertilizers such as compost or seaweed emulsion do not give off such a large concentration of nutrients at once, so these are gentler on the environment. Another way to cut back on the excess water and chemicals used on lawns is to reduce the size of the lawn. The lawn can be bordered with shrubbery and perennial plants, leaving just enough open grass as needed for **recreation**. Another alternative is to replace non-native turf grass with a native grass. Some native grasses stay green all summer, can be mown short, and look very much like a typical lawn. Native buffalo grass (Buchloe dactyloides) has been used successfully for lawns in the South and Southwest. Other native grass species are adapted to other regions. Another example is blue grama grass (Bouteloua gracilis), native to the Great Plains. This grass is tolerant of extreme temperatures and very little rainfall. Some native grasses are best left unmowed, and in some regions homeowners have replaced their lawns with native grass prairies or meadows. In some cases, homeowners have done away with their lawns altogether, using stone or bark **mulch** in its place, or planting a groundcover plant like ivy or wild ginger. These plants might grow between trees, shrubs and perennials, creating a very different look than the traditional green carpet.

For areas with water shortages, or for those who are concerned about conserving **natural resources**, xeriscape landscaping should be considered. Xeriscape comes from the Greek word xeros, meaning dry. Xeriscaping takes advantage of using plants, such as cacti and grasses, such as Mexican feather grass and blue oat grass that thrive in **desert** conditions. Xeriscaping can also include rock gardening as part of the overall landscape plan.

LDC

see **Less developed countries**

LD_{50}

LD_{50} is the dose of a chemical that is lethal to 50 percent of a test population. It is therefore a measure of a particular median response which, in this case, is death. The term is most frequently used to characterize the response of animals such as rats and mice in acute toxicity tests. The term is generally not used in connection with aquatic or inhalation toxicity tests. It is difficult, if not impossible, to determine the dosage of an animal in such tests; results are most commonly represented in terms of lethal concentrations (LC), which refer to the concentration of the substance in the air or water surrounding an animal.

In LD testing, dosages are generally administered by means of injection, food, water, or forced feeding. Injections are used when an animal is to receive only one or a few dosages. Greater numbers of injections would disturb the animal and perhaps generate some false-positive types of responses. Food or water may serve as a good medium for administering a chemical, but the amount of food or water wasted must be carefully noted. Developing a healthy diet for an animal which is compatible with the chemical to be tested can be as much art as science. The chemical may interact with the foods and become more or less toxic, or it may be objectionable to the animal due to taste or odor. Rats are often used in toxicity tests because they do not have the ability to vomit. The investigator therefore has the option of gavage, a way to force-feed rats with a stomach tube or other device when a chemical smells or tastes bad.

A chart showing the increased dose of LD_{50}. (McGraw-Hill Inc. Reproduced by permission.)

Toxicity and LD_{50} are inversely proportional, which means that high toxicity is indicated by a low LD_{50} and vice versa. LD_{50} is a particular type of effective dose (ED) for 50 percent of a population (ED_{50}). The midpoint (or effect on half of the population) is generally used because some individuals in a population may be highly resistant to a particular toxicant, making the dosage at which all individuals respond a misleading data point. Effects other than death, such as headaches or dizziness, might be examined in some tests, so EDs would be reported instead of LDs. One might also wish to report the response of some other percent of the test population, such as the 20 percent response (LD_{20} or ED_{20}) or 80 percent response (LD_{80} or ED_{80}).

The LD is expressed in terms of the mass of test chemical per unit mass of the test animals. In this way, dose is normalized so that the results of tests can be analyzed consistently and perhaps extrapolated to predict the response of animals that are heavier or lighter. Extrapolation of such data is always questionable, especially when extrapolating from animal response to human response, but the system appears to be serving us well. However, it is important to note that sometimes better dose-response relations and extrapolations can be derived through normalizing dosages based on surface area or the weight of target organs. *See also* Bioassay; Dose response; Ecotoxicology; Hazardous material; Toxic substance

Leachate

see **Contaminated soil; Landfill**

Leaching

The process by which soluble substances are dissolved out of a material. When rain falls on farmlands, for example, it dissolves weatherable minerals, pesticides, and fertilizers as it soaks into the ground. If enough water is added to the **soil** to fill all the pores, then water carrying these dissolved materials moves to the groundwater—the soil becomes leached. In soil chemistry, leaching refers to the process by which nutrients in the upper layers of soil are dissolved out and carried into lower layers, where they can be a valuable **nutrient** for plant roots. Leaching also has a number of environmental applications. For example, toxic **chemicals** and radioactive materials stored in sealed containers underground may leach out if the containers break open over time. *See also* Landfill; Leaking underground storage tank

Lead

One of the oldest metals known to humans, lead compounds were used by Egyptians to glaze pottery as far back as 7000 B.C. The toxic effects of lead also have been known for many centuries. In fact, the Romans limited the amount of time slaves could work in lead mines because of the element's harmful effects. Some consequences of lead **poisoning** are **anemia**, headaches, convulsions, and damage to the kidneys and central nervous system. The widespread use of lead in plumbing, **gasoline**, and lead-acid batteries, for example, has made it a serious **environmental health** problem. Bans on the use of lead in motor fuels and paints attempt to deal

with this problem. *See also* Heavy metals and heavy metal poisoning; Lead shot

Lead management

Lead, a naturally occurring bluish gray metal, is extensively used throughout the world in the manufacture of storage batteries, **chemicals** including paint and **gasoline**, and various metal products including sheet lead, solder, pipes, and ammunition. Due to its widespread use, large amounts of lead exist in the **environment**, and substantial quantities of lead continue to be deposited into air, land, and water. Lead is a poison that has many adverse effects, and children are especially susceptible. At present, the production, use, and disposal of lead are regulated with demonstrably effective results. However, because of its previous widespread use and persistence in the environment, lead exposure is a pervasive problem that affects many populations. Effective management of lead requires an understanding of its effects, blood action levels, sources of exposure, and policy responses, topics reviewed in that order.

Effects of Lead

Lead is a strong toxicant that adversely affects many systems in the body. Severe lead exposures can cause brain and kidney damage to adults and children, coma, convulsions, and death. Lower levels, e.g., lead concentrations in blood (PbB) below 50 μg/dL, may impair hemoglobin synthesis, alter the central and peripheral nervous systems, cause hypertension, affect male and female reproductive systems, and damage the developing fetus. These effects depend on the level and duration of exposure and on the distribution and kinetics of lead in the body. Most lead is deposited in bone, and some of this stored lead may be released long after exposure due to a serious illness, pregnancy, or other physiological event. Lead has not been shown to cause **cancer** in humans, however, tumors have developed in rats and mice given large doses of lead and thus several United States agencies consider lead acetate and lead phosphate as human carcinogens.

Children are particularly susceptible to lead **poisoning**. PbB levels as low as 10 μg/dL are associated with decreased intelligence and slowed neurological development. Low PbB levels also have been associated with deficits in growth, vitamin **metabolism**, and effects on hearing. The neurological effects of lead on children are profound and are likely persistent. Unfortunately, childhood exposures to chronic but low lead levels may not produce clinical symptoms, and many cases go undiagnosed and untreated. In recent years, the number of children with elevated blood lead levels has declined substantially. For example, the average PbB level has decreased from over 15 μg/dL in the 1970s to about 5 μg/dL in the 1990s. As described later, these decreases can be attributed to the reduction or elimination of lead in gasoline, food can and plumbing solder, and residential paint. Still, childhood lead poisoning remains the most widespread and preventable childhood health problem associated with environmental exposures, and childhood lead exposure remains a public health concern since blood levels approach or exceed levels believed to cause effects. Though widely perceived as a problem of inner city minority children, lead poisoning affects children from all areas and from all socioeconomic groups.

The definition of a PbB level that defines a level of concern for lead in children continues to be an important issue in the United States. The childhood PbB concentration of concern has been steadily lowered by the Centers for Disease Control (CDC) from 40 μg/dL in 1970 to 10 μg/dL in 1991. The **Environmental Protection Agency** lowered the level of concern to 10 μg/dL ("10-15 and possibly lower") in 1986, and the **Agency for Toxic Substances and Disease Registry** (ATSDR) also identified 10 μg/dL in its 1988 Report to Congress on childhood lead poisoning.

In the workplace, the medical removal PbB concentration is 50 μg/dL for three consecutive checks and 60 μg/dL for any single check. Blood level monitoring is triggered by an air lead concentration above 30 $\mu g/m^3$. A worker is permitted to return to work when his blood lead level falls below 40 μg/dL. In 1991, the National Institute for Occupational Safety and Health (NIOSH) set a goal of eliminating occupational exposures that result in workers having PbB levels greater than 25 μg/dL.

Exposure and Sources

Lead is a persistent and ubiquitous pollutant. Since it is an elemental pollutant, it does not dissipate, biodegrade, or decay. Thus, the total amount of lead pollutants resulting from human activity increases over time, no matter how little additional lead is added to the environment. Lead is a multi-media pollutant, i.e., many sources contribute to the overall problem, and exposures from air, water, **soil**, dust, and food pathways may be important.

For children, an important source of lead exposure is from swallowing nonfood items, an activity known as pica (an abnormal eating habit e.g., chips of lead-containing paint), most prevalent in 2 and 3 year-olds. Children who put toys or other items in their mouths may also swallow lead if lead-containing dust and dirt are on these items. Touching dust and dirt containing lead is commonplace, but relatively little lead passes through the skin. The most important source of high-level lead exposure in the United States is household dust derived from deteriorated lead-based paint. Numerous homes contain lead-based paint and continue to be occupied by families with small children, including 21 million pre-1940 homes and rental units which,

over time, are rented to different families. Thus, a single house with deteriorated lead-based paint can be the source of exposure for many children.

In addition to lead-based paint in houses, other important sources of lead exposure include (1) **contaminated soil** and dust from deteriorated paints originally applied to buildings, bridges, and water tanks; (2) drinking water into which lead has leached from lead, bronze, or brass pipes and fixtures (including lead-soldered pipe joints) in houses, schools, and public buildings; (3) occupational exposures in smelting and refining industries, steel welding and cutting operations, battery manufacturing plants, gasoline stations, and radiator repair shops; (4) airborne lead from smelters and other point sources of **air pollution**, including vehicles burning leaded fuels; (5) **hazardous waste** sites which contaminate soil and water; (6) food cans made with lead-containing solder and pottery made with lead-containing glaze; and (7) food consumption if crops are grown using fertilizers that contain sewage **sludge** or if much lead-containing dust is deposited onto crops. In the **atmosphere**, the use of leaded gasoline has been the single largest source of lead (90%) since the 1920s, although the use of leaded fuel has been greatly curtailed and gasoline contributions are now greatly reduced (35%). As discussed below, leaded fuel and many other sources have been greatly reduced in the United States, although drinking water and other sources remain important in some areas. A number of other countries, however, continue to use leaded fuel and other lead-containing products.

Government Responses

Many agencies are concerned with lead management. Lead agencies in the United States include the Environmental Protection Agency, the Centers for Disease Control, the **U.S. Department of Health and Human Services**, the Department of Housing and Urban Development, the **Food and Drug Administration**, the Consumer Product Safety Commission, the National Institute for Occupational Safety and Health, and the **Occupational Safety and Health Administration**. These agencies have taken many actions to reduce lead exposures, several of which have been very successful. General types of actions include: (1) restrictions or bans on the use of many products containing lead where risks from these products are high and where substitute products are available, e.g., interior paints, gasoline fuels, and solder; (2) **recycling** and safer ultimate disposal strategies for products where risks are lower, or for which technically and economically feasible substitutes are not available, e.g., lead-acid automotive batteries, lead-containing wastes, pigments and used oil; (3) **emission** controls for lead smelters, primary metal industries, and other industrial point sources, including the use of the best practicable control technology (BPCT) for new lead smelting and processing facilities and reasonable available control technologies (RACT) for existing facilities, and; (4) education and abatement programs where exposure is based on past uses of lead.

The current goals of the Environmental Protection Agency (EPA) strategy are to reduce lead exposures to the fullest extent practicable, to significantly reduce the incidence of PbB levels above 10 μg/dL in children, and to reduce lead exposures that are anticipated to pose risks to children, the general public, or the environment. Several specific actions of this and other agencies are discussed below.

The Residential Lead-based Paint Hazard Reduction Act of 1992 (Title X) provides the framework to reduce hazards from lead-based paint exposure, primarily in housing. It establishes a national infrastructure of trained workers, training programs and proficient laboratories, and a public education program to reduce hazards from lead exposure in paint in the nation's housing stock. Earlier, to help protect small children who might swallow chips of paint, the Consumer Product Safety Commission (CPSC) restricted the amount of lead in most paints to 0.06 percent by weight. CDC further suggests that inside and outside paint used in buildings where people live be tested for lead. If the level of lead is high, the paint should be removed and replaced with a paint that contains an allowable level of lead. CPSC published a consumer safety alert/brochure on lead paint in the home in 1990, and has evaluated lead test kits for safety, efficacy, and consumer-friendliness. These kits are potential screening devices that may be used by the consumer to detect lead in paint and other materials. Title X also requires EPA to promulgate regulations that ensure personnel engaged in abatement activities are trained, to certify training programs, to establish standards for abatement activities, to promulgate model state programs, to establish a laboratory accreditation program, to establish a information clearinghouse, and to disclose lead hazards at property transfer.

The Department of Housing and Urban Development (HUD) has begun activities that include updating regulations dealing with lead-based paint in HUD programs and federal property; providing support for local screening programs; increasing public education; supporting research to reduce the cost and improve the reliability of testing and abatement; increasing state and local support; and providing more money to support abatement in low and moderate income households. HUD estimated that the total cost of testing and abatement in high-priority hazard homes will be $8 to 10 billion annually over 10 years, although costs could be substantially lowered by integrating abatement with other renovation activities.

CPSC, EPA, and states are required by the Lead Contamination Control Act of 1988 to test drinking water in schools for lead and to remove lead if levels are too high.

Drinking water coolers must also be lead-free and any that contain lead must be removed. EPA regulations limit lead in drinking water to 0.015 mg/L.

To manage environmental exposures resulting from inhalation, EPA regulations limit lead to 0.1 and 0.05 g/gal (0.38 and 0.19 g/L) in leaded and unleaded gasoline, respectively. Also, the National Ambient Air Quality Standards set a maximum lead concentrations of 1.5 $\mu g/m^3$ using a three month average, although typical levels are far lower, 0.1 or 0.2 $\mu g/m^3$.

To identify and mitigate sources of lead in the diet, the Food and Drug Administration (FDA) has undertaken efforts that include voluntary discontinuation of lead solder in food cans by the domestic food industry, and elimination of lead in glazing on ceramic ware. Regulatory measures are being introduced for wine, dietary supplements, crystal ware, **food additives**, and bottled water.

For workers in lead-using industries, the Occupational Safety and Health Administration (OSHA) has established environmental and biological standards that include maximum air and blood levels. This monitoring must be conducted by the employer, and elevated PbB levels may require the removal of an individual from the work place (levels discussed previously). The Permissible Exposure Level (PEL) limits air concentrations of lead to 50 $\mu g/m^3$, and, if 30 $\mu g/m^3$ is exceeded, employers must implement a program that includes medical surveillance, exposure monitoring, training, regulated areas, respiratory protection, protective work clothing and equipment, housekeeping, hygiene facilities and practices, signs and labels, and record keeping. In the construction industry, the PEL is 200 $\mu g/m^3$. The National Institute for Occupational Safety and Health (NIOSH) recommends that workers not be exposed to levels of more than 100 $\mu g/m^3$ for up to 10 hours, and NIOSH has issued a health alert to construction workers regarding possible adverse health effects from long-term and low-level exposure. NIOSH has also published alerts and recommendations for preventing lead poisoning during blasting, sanding, cutting, burning, or welding of bridges and other steel structures coated with lead paint.

Finally, lead screening for children has recently increased. The CDC recommends that screening (testing) for lead poisoning be included in health care programs for children under 72 months of age, especially those under 36 months of age. For a community with a significant number of children having PbB levels between 10-14 $\mu g/dL$, community-wide lead poisoning prevention activities should be initiated. For individual children with PbB levels between 15-19 $\mu g/dL$, nutritional and educational interventions are recommended. PbB levels exceeding 20 $\mu g/dL$ should trigger investigations of the affected individual's environment and medical evaluations. The highest levels, above 45 $\mu g/dL$, require both medical and environmental interventions, including chelation therapy. CDC also conducts studies to determine the impact of interventions on children's blood lead levels.

These regulatory activities have resulted in significant reductions in average levels of lead exposure. Nevertheless, lead management remains an important public health problem.

[*Stuart Batterman*]

Lead shot

Lead shot refers to the small pellets that are fired by shotguns while **hunting** waterfowl or upland fowl, or while skeet shooting. Most lead shots miss their target and are dissipated into the **environment**. Because the shot is within the particle-size range that is favored by medium-sized birds as grit, it is often ingested and retained in the gizzard to aid in the mechanical abrasion of plant seeds, the first step in avian digestion. However, the shot also abrades during this process, releasing toxic lead that can poison the bird. It has been estimated that as much as 2–3 percent of the North American waterfowl population, or several million birds, may die from shot-caused lead **poisoning** each year. This problem will decrease in intensity, however, because lead shot is now being substantially replaced by steel shot in North America. *See also* Heavy metals and heavy metal poisoning

Leafy spurge

Leafy spurge (*Euphorbia esula* L.), a perennial plant from Europe and Asia, was introduced to North America through imported grain products by 1827. It is 12 in (30.5 cm) to 3 ft (1 m) in height. Stems, leaves, and roots contain milky white latex which contains toxic cardiac glycosides that is distasteful to cattle, who will not eat it. Considered a noxious, or destructive, weed in southern Canada and the northern

Great Plains of the United States, it crowds out native rangeland grasses, reducing the number of cattle that can graze the land. It is responsible for losses of approximately 35–45 million dollars per year to the United States cattle and hay industries. Its aggressive root system makes controlling spread difficult. Roots spread vertically to 15 ft (5 m) with up to 300 root buds, and horizontally to nearly 30 ft (9 m). It regenerates from small portions of root. Tilling, burning, and **herbicide** use are ineffective control methods as roots are not damaged and may prevent immediate regrowth of the desired **species**. The introduction of specific herbivores of the leafy spurge from its native range, including certain species of beetles and moths, may be an effective means of control, as may be certain pathogenic **fungi**. Studies also indicate sheep and Angora goats will eat it. To control this plant's rampant spread in North America, a combination of methods seems most effective.

[*Monica Anderson*]

League of Conservation Voters

In 1970 Marion Edey, a House committee staffer, founded the League of Conservation Voters (LCV) as the non-partisan political action arm of the United States' environmental movement. LCV works to establish a pro-environment—or "green"—majority in Congress and to elect environmentally conscious candidates throughout the country. Through campaign donations, volunteers, and endorsements, pro-environment advertisements, and annual publications such as the *National Environmental Scorecard*, the League raises voter awareness of the environmental positions of candidates and elected officials.

Technically it has no formal membership, but the League's supporters—who make donations and purchase its publications—number 100,000. The board of directors is comprised of 24 important environmentalists associated with such organizations as the **Sierra Club**, the **Environmental Defense** Fund, and **Friends of the Earth**. Because these organizations would endanger their charitable tax status if they participated directly in the electoral process, environmentalists developed the League. Since 1970 LCV has influenced many elections.

From its first effort in 1970—wherein LCV successfully prevented Rep. Wayne Aspinall of Colorado from obtaining a democratic nomination—the League has grown to be a significant force in American politics. In the 1989–90 elections LCV supported 120 pro-environment candidates and spent approximately $250,000 on their campaigns. In 1990 the League developed new endorsement tactics. First it invented the term "greenscam" to identify candidates who only appear green. Next LCV produced two generic television advertisements for candidates. One advertisement, entitled "Greenscam," attacked the aforementioned candidates; the other, entitled "Decisions," was an award-winning, positive advertisement in support of pro-environment candidates. By the 2000 campaign the League had attained an unprecedented degree of influence in the electoral process. That year LCV raised and donated 4.1 million dollars in support of both Democratic and Republican candidates in a variety of ways.

In endorsing a candidate the League no longer simply contributes money to a campaign. It provides "in-kind" assistance—for example, it places a trained field organizer on a staff, creates radio and television advertisements, or develops grassroots outreach programs and campaign literature. In addition to supporting specific candidates, LCV holds all elected officials accountable for their track records on environmental issues. The League's annual publication *National Environmental Scorecard* lists the voting records of House and Senate members on environmental legislation. Likewise, the *Presidential Scorecard* identifies the positions that presidential candidates have taken. Through these publications and direct endorsement strategies, the League continues to apply pressure in the political process and elicit support for the **environment**

Louis Seymour Bazett Leakey (1903 – 1972)

African-born English paleontologist and anthropologist

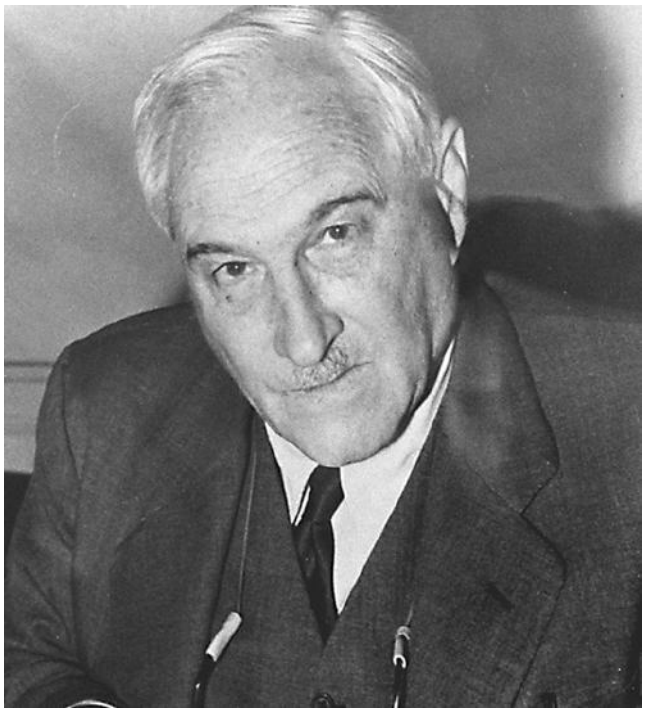
Louis Seymour Bazett Leakey was born on August 7, 1903, in Kabete, Kenya. His parents, Mary Bazett (d. 1948) and Harry Leakey (1868–1940) were Church of England missionaries at the Church Missionary Society, Kabete, Kenya. Louis spent his childhood in the mission, where he learned the Kikuyu language and customs (he later compiled a Kikuyu grammar book). As a child, while pursuing his interest in ornithology—the study of birds—he often found stone tools washed out of the **soil** by the heavy rains, which Leakey believed were of prehistoric origin. Stone tools were primary evidence of the presence of humans at a particular site, as toolmaking was believed at the time to be practiced only by

humans and was, along with an erect posture, one of the chief characteristics used to differentiate humans from nonhumans. Scientists at the time, however, did not consider East Africa a likely site for finding evidence of early humans; the discovery of *Pithecanthropus* in Java in 1894 (the so-called Java Man, now considered to be an example of *Homo erectus*) had led scientists to assume that Asia was the continent from which human forms had spread.

Shortly after the end of World War I, Leakey was sent to a public school in Weymouth, England, and later attended St. John's College, Cambridge. Suffering from severe headaches resulting from a sports injury, he took a year off from his studies and joined a fossil-hunting expedition to Tanganyika (now Tanzania). This experience, combined with his studies in anthropology at Cambridge (culminating in a degree in 1926), led Leakey to devote his time to the search for the origins of humanity, which he believed would be found in Africa. Anatomist and anthropologist Raymond A. Dart's discovery of early human remains in South Africa was the first concrete evidence that this view was correct. Leakey's next expedition was to northwest Kenya, near Lakes Nakuru and Naivasha, where he uncovered materials from the Late Stone Age; at Kariandusi he discovered a 200,000-year-old hand ax.

In 1928 Leakey married Henrietta Wilfrida Avern, with whom he had two children: Priscilla, born in 1930, and Colin, born in 1933; the couple was divorced in the mid-1930s. In 1931 Leakey made his first trip to Olduvai Gorge—a 350-mi (564-km) ravine in Tanzania—the site that was to be his richest source of human remains. He had been discouraged from excavating at Olduvai by Hans Reck, a German paleontologist who had fruitlessly sought evidence of prehistoric humans there. Leakey's first discoveries at that site consisted of both animal fossils, important in the attempts to date the particular stratum (or layer of earth) in which they were found, and, significantly, flint tools. These tools, dated to approximately one million years ago, were conclusive evidence of the presence of hominids—a family of erect primate mammals that use only two feet for locomotion—in Africa at that early date; it was not until 1959, however, that the first fossilized hominid remains were found there.

In 1932, near Lake Victoria, Leakey found remains of *Homo sapiens* (modern man), the so-called Kanjera skulls (dated to 100,000 years ago) and Kanam jaw (dated to 500,000 years ago); Leakey's claims for the antiquity of this jaw made it a controversial find among other paleontologists, and Leakey hoped he would find other, independent, evidence for the existence of *Homo sapiens* from an even earlier period—the Lower Pleistocene.



In the mid-1930s, a short time after his divorce from Wilfrida, Leakey married his second wife, Mary Douglas Nicol; she was to make some of the most significant discoveries of Leakey's team's research. The couple eventually had three children: Philip, Jonathan, and Richard E. Leakey. During the 1930s, Leakey also became interested in the study of the Paleolithic period in Britain, both regarding human remains and geology, and he and Mary Leakey carried out excavations at Clacton in southeast England.

Until the end of the 1930s, Leakey concentrated on the discovery of stone tools as evidence of human habitation; after this period he devoted more time to the unearthing of human and prehuman fossils. His expeditions to Rusinga Island, at the mouth of the Kavirondo Gulf in Kenya, during the 1930s and early 1940s produced a large number of finds, especially of remains of Miocene apes. One of these apes, which Leakey named *Proconsul africanus,* had a jaw lacking in the so-called simian shelf that normally characterized the jaws of apes; this was evidence that *Proconsul* represented a stage in the progression from ancient apes to humans. In 1948 Mary Leakey found a nearly complete *Proconsul* skull, the first fossil ape skull ever unearthed; this was followed by the unearthing of several more *Proconsul* remains.

Louis Leakey began his first regular excavations at Olduvai Gorge in 1952; however, the Mau Mau (an anti-white secret society) uprising in Kenya in the early 1950s disrupted his paleontological work and induced him to write *Mau Mau and the Kikuyu*, in an effort to explain the rebellion from the perspective of a European with an insider's knowledge of the Kikuyu. A second work, *Defeating Mau Mau*, followed in 1954.

During the late 1950s, the Leakeys continued their work at Olduvai. In 1959, while Louis was recuperating from an illness, Mary Leakey found substantial fragments of a hominid skull that resembled the robust australopithecines—African hominids possessing small brains and near-human dentition—found in South Africa earlier in the century. Louis Leakey, who quickly reported the find to the journal *Nature*, suggested that this represented a new genus, which he named *Zinjanthropus boisei*, the genus name meaning "East African man," and the **species** name commemorating Charles Boise, one of Leakey's benefactors. This species, now called *Australopithecus boisei*, was later believed by Leakey to have been an evolutionary dead end, existing contemporaneously with *Homo* rather than representing an earlier developmental stage.

In 1961, at Fort Ternan, Leakey's team located fragments of a jaw that Leakey believed were from a hitherto unknown genus and species of ape, one he designated as *Kenyapithecus wickeri*, and which he believed was a link between ancient apes and humans, dating from 14 million years ago; it therefore represented the earliest hominid. In 1967, however, an older skull, one that had been found two decades earlier on Rusinga Island and which Leakey had

Louis Leakey. (The Library of Congress.)

originally given the name *Ramapithecus africanus*, was found to have hominid-like lower dentition; he renamed it *Kenyapithecus africanus*, and Leakey believed it was an even earlier hominid than *Kenyapithecus wickeri*. Leakey's theories about the place of these Lower Miocene fossil apes in human **evolution** have been among his most widely disputed.

During the early 1960s, a member of Leakey's team found fragments of the hand, foot, and leg bones of two individuals, in a site near where *Zinjanthropus* had been found, but in a slightly lower and, apparently, slightly older layer. These bones appeared to be of a creature more like modern humans than *Zinjanthropus*, possibly a species of *Homo* that lived at approximately the same time, with a larger brain and the ability to walk fully upright. As a result of the newly developed potassium-argon dating method, it was discovered that the bed from which these bones had come was 1.75 million years old. The bones were, apparently, the evidence for which Leakey had been searching for years: skeletal remains of *Homo* from the Lower Pleistocene. Leakey designated the creature whose remains these were as *Homo habilis* ("man with ability"), a creature who walked upright and had dentition resembling that of modern humans, hands capable of toolmaking, and a large cranial capacity. Leakey saw this hominid as a direct ancestor of *Homo erectus* and modern humans. Not unexpectedly, Leakey was attacked by other scholars, as this identification of the fragments moved the origins of the genus *Homo* back substantially further in time. Some scholars felt that the new remains were those of australopithecines, if relatively advanced ones, rather than very early examples of *Homo*.

Health problems during the 1960s curtailed Leakey's field work; it was at this time that his Centre for Prehistory and Paleontology in Nairobi became the springboard for the careers of such paleontologists as **Jane Goodall** and Dian Fossey in the study of nonhuman primates. A request came in 1964 from the Israeli government for assistance with the technical as well as the fundraising aspects involved in the excavation of an early Pleistocene site at Ubeidiya. This produced evidence of human habitation dating back 700,000 years, the earliest such find outside Africa.

During the 1960s, others, including Mary Leakey and the Leakeys' son Richard, made significant finds in East Africa; Leakey turned his attention to the investigation of a problem that had intrigued him since his college days: the determination of when humans had reached the North American continent. Concentrating his investigation in the Calico Hills in the Mojave **Desert**, California, he sought evidence in the form of stone tools of the presence of early humans, as he had done in East Africa. The discovery of some pieces of chalcedony (translucent quartz) that resembled manufactured tools in **sediment** dated from 50,000 to 100,000 years old stirred an immediate controversy; at that time, scientists believed that humans had settled in North America approximately 20,000 years ago. Many archaeologists, including Mary Leakey, criticized Leakey's California methodology—and his interpretations of the finds—as scientifically unsound, but Leakey, still charismatic and persuasive, was successful in obtaining funding from the National Geographic Society and, later, several other sources. Human remains were not found in conjunction with the supposed stone tools, and many scientists have not accepted these "artifacts" as anything other than rocks.

Shortly before Louis Leakey's death, Richard Leakey showed his father a skull he had recently found near Lake Rudolf (now Lake Turkana) in Kenya. This skull, removed from a deposit dated to 2.9 million years ago, had a cranial capacity of approximately 800 cubic centimeters, putting it within the range of *Homo* and apparently vindicating Leakey's long-held belief in the extreme antiquity of that genus; it also appeared to substantiate Leakey's interpretation of the Kanam jaw. Leakey died of a heart attack in early October, 1972, in London.

Some scientists have questioned Leakey's interpretations of his discoveries. Other scholars have pointed out that two of the most important finds associated with him were actually made by Mary Leakey, but became widely known when they were interpreted and publicized by him; Leakey had even encouraged criticism through his tendency to publi-

cize his somewhat sensationalistic theories before they had been sufficiently tested. Critics have cited both his tendency toward hyperbole and his penchant for claiming that his finds were the "oldest," the "first," the "most significant"; in a 1965 *National Geographic* article, for example, Melvin M. Payne pointed out that Leakey, at a Washington, D.C., press conference, claimed that his discovery of *Homo habilis* had made all previous scholarship on early humans obsolete. Leakey has also been criticized for his eagerness to create new genera and species for new finds, rather than trying to fit them into existing categories. Leakey, however, recognized the value of publicity for the fundraising efforts necessary for his expeditions. He was known as an ambitious man, with a penchant for stubbornly adhering to his interpretations, and he used the force of his personality to communicate his various finds and the subsequent theories he devised to scholars and the general public.

Leakey's response to criticism was that scientists have trouble divesting themselves of their own theories in the light of new evidence. "Theories on prehistory and early man constantly change as new evidence comes to light," Leakey remarked, as quoted by Payne in *National Geographic.* "A single find such as *Homo habilis* can upset long-held—and reluctantly discarded—concepts. A paucity of human fossil material and the necessity for filling in blank spaces extending through hundreds of thousands of years all contribute to a divergence of interpretations. But this is all we have to work with; we must make the best of it within the limited range of our present knowledge and experience." Much of the controversy derives from the lack of consensus among scientists about what defines "human"; to what extent are toolmaking, dentition, cranial capacity, and an upright posture defining characteristics, as Leakey asserted?

Louis Leakey's significance revolves around the ways in which he changed views of early human development. He pushed back the date when the first humans appeared to a time earlier than had been believed on the basis of previous research. He showed that human evolution began in Africa rather than Asia, as had been maintained. In addition, he created research facilities in Africa and stimulated explorations in related fields, such as primatology (the study of primates). His work is notable as well for the sheer number of finds—not only of the remains of apes and humans, but also of the plant and animal species that comprised the ecosystems in which they lived. These finds of Leakey and his team filled numerous gaps in scientific knowledge of the evolution of human forms. They provided clues to the links between prehuman, apelike primates, and early humans, and demonstrated that human evolution may have followed more than one parallel path, one of which led to modern humans, rather than a single line, as earlier scientists had maintained.

Mary Douglas Nicol Leakey (1913 – 1996)

English paleontologist and anthropologist

For many years Mary Leakey lived in the shadow of her husband, Louis Leakey, whose reputation, coupled with the prejudices of the time, led him to be credited with some of his wife's discoveries in the field of early human archaeology. Yet she has established a substantial reputation in her own right and has come to be recognized as one of the most important paleoanthropologists of the twentieth century. It was Mary Leakey who was responsible for some of the most important discoveries made by Louis Leakey's team. Although her close association with Louis Leakey's work on Paleolithic sites at Olduvai Gorge—a 350-mi (564-km) ravine in Tanzania—has led to her being considered a specialist in that particular area and period, she has in fact worked on excavations dating from as early as the Miocene Age (an era dating to approximately 18 million years ago) to those as recent as the Iron Age of a few thousand years ago.

Mary Leakey was born Mary Douglas Nicol on February 6, 1913, in London. Her mother was Cecilia Frere, the great-granddaughter of John Frere, who had discovered prehistoric stone tools at Hoxne, Suffolk, England, in 1797. Her father was Erskine Nicol, a painter who himself was the son of an artist, and who had a deep interest in Egyptian archaeology. When Mary was a child, her family made frequent trips to southwestern France, where her father took her to see the Upper Paleolithic cave paintings. She and her father became friends with Elie Peyrony, the curator of the local museum, and there she was exposed to the vast collection of flint tools dating from that period of human prehistory. She was also allowed to accompany Peyrony on his excavations, though the archaeological work was not conducted in what would now be considered a scientific way—artifacts were removed from the site without careful study of the place in the earth where each had been found, obscuring valuable data that could be used in dating the artifact and analyzing its context. On a later trip, in 1925, she was taken

to Paleolithic caves by the Abbe Lemozi of France, parish priest of Cabrerets, who had written papers on cave art. After her father's death in 1926, Mary Nicol was taken to Stonehenge and Avebury in England, where she began to learn about the archaeological activity in that country and, after meeting the archaeologist Dorothy Liddell, to realize the possibility of archaeology as a career for a woman.

By 1930 Mary Nicol had undertaken coursework in geology and archaeology at the University of London and had participated in a few excavations in order to obtain field experience. One of her lecturers, R. E. M. Wheeler, offered her the opportunity to join his party excavating St. Albans, England, the ancient Roman site of Verulamium; although she only remained at that site for a few days, finding the work there poorly organized, she began her career in earnest shortly thereafter, excavating Neolithic (early Stone Age) sites in Henbury, Devon, where she worked between 1930 and 1934. Her main area of expertise was stone tools, and she was exceptionally skilled at making drawings of them. During the 1930s Mary met Louis Leakey, who was to become her husband. Leakey was by this time well known because of his finds of early human remains in East Africa; it was at Mary and Louis's first meeting that he asked her to help him with the illustrations for his 1934 book, *Adam's Ancestors: An Up-to-Date Outline of What Is Known about the Origin of Man*.

In 1934 Mary Nicol and Louis Leakey worked at an excavation in Clacton, England, where the skull of a hominid—a family of erect primate mammals that use only two feet for locomotion—had recently been found and where Louis was investigating Paleolithic geology as well as **fauna** and human remains. The excavation led to Mary Leakey's first publication, a 1937 report in the *Proceedings of the Prehistoric Society*.

By this time, Louis Leakey had decided that Mary should join him on his next expedition to Olduvai Gorge in Tanganyika (now Tanzania), which he believed to be the most promising site for discovering early Paleolithic human remains. On the journey to Olduvai, Mary stopped briefly in South Africa, where she spent a few weeks with an archaeological team and learned more about the scientific approach to excavation, studying each find *in situ*—paying close attention to the details of the geological and faunal material surrounding each artifact. This knowledge was to assist her in her later work at Olduvai and elsewhere.

At Olduvai, among her earliest discoveries were fragments of a human skull; these were some of the first such remains found at the site, and it would be twenty years before any others would be found there. Mary Nicol and Louis Leakey returned to England. Leakey's divorce from his first wife was made final in the mid-1930s, and he and Mary Nicol were then married; the couple returned to Kenya in January of 1937. Over the next few years, the Leakeys excavated Neolithic and Iron Age sites at Hyrax Hill, Njoro River Cave, and the Naivasha Railway Rock Shelter, which yielded a large number of human remains and artifacts.

During World War II, the Leakeys began to excavate at Olorgasailie, southwest of Nairobi, but because of the complicated geology of that site, the dating of material found there was difficult. It did prove to be a rich source of material, however; in 1942 Mary Leakey uncovered hundreds, possibly thousands, of hand axes there. Her first major discovery in the field of prehuman fossils was that of most of the skull of a *Proconsul africanus* on Rusinga Island, in Lake Victoria, Kenya, in 1948. *Proconsul* was believed by some paleontologists to be a common ancestor of apes and humans, an animal whose descendants developed into two branches on the evolutionary tree: the *Pongidae* (great apes) and the *Hominidae* (who eventually evolved into true humans). *Proconsul* lived during the Miocene Age, approximately 18 million years ago. This was the first time a fossil ape skull had ever been found—only a small number have been found since—and the Leakeys hoped that this would be the ancestral hominid that paleontologists had sought for decades. The absence of a "simian shelf," a reinforcement of the jaw found in modern apes, is one of the features of *Proconsul* that led the Leakeys to infer that this was a direct ancestor of modern humans. *Proconsul* is now generally believed to be a **species** of *Dryopithecus*, closer to apes than to humans.

Many of the finds at Olduvai were primitive stone hand axes, evidence of human habitation; it was not known, however, who had made them. Mary's concentration had been on the discovery of such tools, while Louis's goal had been to learn who had made them, in the hope that the date for the appearance of toolmaking hominids could be moved back to an earlier point. In 1959 Mary unearthed part of the jaw of an early hominid she designated *Zinjanthropus* (meaning "East African Man") and whom she referred to as "Dear Boy"; the early hominid is now considered to be a species of *Australopithecus*—apparently related to the two kinds of australopithecine found in South Africa, *Australopithecus africanus* and *Australopithecus robustus*— and given the species designation *boisei* in honor of Louis Leakey's sponsor Charles Boise. By means of potassium-argon dating, recently developed, it was determined that the fragment was 1.75 million years old, and this realization pushed back the date for the appearance of hominids in Africa. Despite the importance of this find, however, Louis Leakey was slightly disappointed, as he had hoped that the excavations would unearth not another australopithecine, but an example of *Homo* living at that early date. He was seeking evidence for his theory that more than one hominid form lived at Olduvai at the same time; these forms were the australopithecines, who eventually died out, and some early form of *Homo*, which

survived—owing to toolmaking ability and larger cranial capacity—to evolve into *Homo erectus* and, eventually, the modern human. Leakey hoped that Mary Leakey's find would prove that *Homo* existed at that early level of Olduvai. The discovery he awaited did not come until the early 1960s, with the identification of a skull found by their son Jonathan Leakey that Louis designated as *Homohabilis* ("man with ability"). He believed this to be the true early human responsible for making the tools found at the site.

In her autobiography, *Disclosing the Past*, released in 1984, Mary Leakey reveals that her professional and personal relationship with Louis Leakey had begun to deteriorate by 1968. As she increasingly began to lead the Olduvai research on her own, and as she developed a reputation in her own right through her numerous publications of research results, she believes that her husband began to feel threatened. Louis Leakey had been spending a vast amount of his time in fundraising and administrative matters, while Mary was able to concentrate on field work. As Louis began to seek recognition in new areas, most notably in excavations seeking evidence of early humans in California, Mary stepped up her work at Olduvai, and the breach between them widened. She became critical of his interpretations of his California finds, viewing them as evidence of a decline in his scientific rigor. During these years at Olduvai, Mary made numerous new discoveries, including the first *Homo erectus* pelvis to be found. Mary Leakey continued her work after Louis Leakey's death in 1972. From 1975 she concentrated on Laetoli, Tanzania, which was a site earlier than the oldest beds at Olduvai. She knew that the lava above the Laetoli beds was dated to 2.4 million years ago, and the beds themselves were therefore even older; in contrast, the oldest beds at Olduvai were two million years old. Potassium-argon dating has since shown the upper beds at Laetoli to be approximately 3.5 million years old. In 1978 members of her team found two trails of hominid footprints in volcanic ash dated to approximately 3.5 million years ago; the form of the footprints gave evidence that these hominids walked upright, thus moving the date for the development of an upright posture back significantly earlier than previously believed. Mary Leakey considers these footprints to be among the most significant finds with which she has been associated.

In the late 1960s Mary Leakey received an honorary doctorate from the University of the Witwatersrand in South Africa, an honor she accepted only after university officials had spoken out against apartheid. Among her other honorary degrees are a D.S.Sc. from Yale University and a D.Sc. from the University of Chicago. She received an honorary D.Litt. from Oxford University in 1981. She has also received the Gold Medal of the Society of Women Geographers.

Louis Leakey was sometimes faulted for being too quick to interpret the finds of his team and for his propensity for developing sensationalistic, publicity-attracting theories. In recent years Mary Leakey had been critical of the conclusions reached by her husband—as well as by some others—but she did not add her own interpretations to the mix. Instead, she has always been more concerned with the act of discovery itself; she wrote that it is more important for her to continue the task of uncovering early human remains to provide the pieces of the puzzle than it is to speculate and develop her own interpretations. Her legacy lies in the vast amount of material she and her team have unearthed; she leaves it to future scholars to deduce its meaning.

Richard Erskine Frere Leakey (1944 –)

African-born English paleontologist and anthropologist

Richard Erskine Frere Leakey was born on December 19, 1944, in Nairobi, Kenya. Continuing the work of his parents, Leakey has pushed the date for the appearance of the first true humans back even further than they had, to nearly three million years ago. This represents nearly a doubling of the previous estimates. Leakey also has found more evidence to support his father's still controversial theory that there were at least two parallel branches of human **evolution**, of which only one was successful. The abundance of human fossils uncovered by Richard Leakey's team has provided an enormous number of clues as to how the various fossil remains fit into the puzzle of human evolution. The team's finds have also helped to answer, if only speculatively, some basic questions: When did modern human's ancestors split off from the ancient apes? On what continent did this take place? At what point did they develop the characteristics now considered as defining human attributes? What is the relationship among and the chronology of the various genera and **species** of the fossil remains that have been found?

While accompanying his parents on an excavation at Kanjera near Lake Victoria at the age of six, Richard Leakey made his first discovery of fossilized animal remains, part of an extinct variety of giant pig. Richard Leakey, however, was determined not to "ride upon his parents' shoulders," as Mary Leakey wrote in her autobiography, *Disclosing the Past*. Several years later, as a young teenager in the early 1960s, Richard demonstrated a talent for **trapping wildlife**, which prompted him to drop out of high school to lead photographic safaris in Kenya. His paleontological career began in 1963, when he led a team of paleontologists to a fossil-bearing area near Lake Natron in Tanganyika (now Tanzania), a site that was later dated to approximately 1.4 million years ago. A member of the team discovered the jaw of an early hominid—a member of the family of erect primate mammals that use only two feet for locomotion—called an *Australopithecus boisei* (then named *Zinjanthropus*).) This was the first discovery of a complete *Australopithecus* lower jaw and the only *Australopithecus* skull fragment found since Mary Leakey's landmark discovery in 1959. Jaws provide essential clues about the nature of a hominid, both in terms of its structural similarity to other species and, if teeth are present, its diet. Richard Leakey spent the next few years occupied with more excavations, the most important result of which was the discovery of a nearly complete fossil elephant.

In 1964 Richard married Margaret Cropper, who had been a member of his father's team at Olduvai the year before. It was at this time that he became associated with his father's Centre for Prehistory and Paleontology in Nairobi. In 1968, at the age of 23, he became administrative director of the National Museum of Kenya.

While his parents had mined with great success the fossil-rich Olduvai Gorge, Richard Leakey concentrated his efforts in northern Kenya and southern Ethiopia. In 1967 he served as the leader of an expedition to the Omo Delta area of southern Ethiopia, a trip financed by the National Geographic Society. In a site dated to approximately 150,000 years ago, members of his team located portions of two fossilized human skulls believed to be from examples of *Homo sapiens*, or modern humans. While the prevailing view at the time was that *Homo sapiens* emerged around 60,000 years ago, these skulls were dated at 130,000 years old.

While on an airplane trip, Richard Leakey flew over the eastern portion of Lake Rudolf (now Lake Turkana) on the Ethiopia-Kenya border, and he noticed from the air what appeared to be ancient lake sediments, a kind of terrain that he felt looked promising as an excavation site. He used his next National Geographic Society grant to explore this area. The region was Koobi Fora, a site that was to become Richard Leakey's most important area for excavation. At Koobi Fora his team uncovered more than four hundred hominid fossils and an abundance of stone tools, such tools being a primary indication of the presence of early humans. Subsequent excavations near the Omo River in Kenya, from 1968, unearthed more examples of early humans, the first found being another *Australopithecus* lower jaw fragment. At the area of Koobi Fora known as the KBS tuff (tuff being volcanic ash; KBS standing for the Kay Behrensmeyer Site, after a member of the team) stone tools were found. Preliminary dating of the site placed the area at 2.6 million years ago; subsequent tests over the following few years determined the now generally accepted age of 1.89 million years.

In July of 1969, Richard Leakey came across a virtually complete *Australopithecus boisei* skull—lacking only the teeth and lower jaw—lying in a river bed. A few days later a member of the team located another hominid skull nearby, comprising the back and base of the cranium. The following year brought the discovery of many more fossil hominid remains, at the rate of nearly two per week. Among the most important finds was the first hominid femur to be found in Kenya, which was soon followed by several more. It was at about this time that Leakey obtained a divorce from his first wife, and in October of 1970, he married Meave Gillian Epps, who had been on the 1969 expedition.

In 1972, Richard Leakey's team uncovered a skull that appeared to be similar to the one identified by his father and called *Homo habilis* ("man with ability"). This was the early human that Louis Leakey maintained had achieved the toolmaking skills that precipitated the development of a larger brain capacity and led to the development of the modern human—*Homo sapiens*. This skull was more complete and apparently somewhat older than the one Louis Leakey had found and was thus the earliest example of the species *Homo* yet discovered. They labeled the new skull, which was found below the KBS tuff, "Skull 1470," and this proved to among Richard Leakey's most significant discoveries. The fragments consisted of small pieces of all sides of the cranium, and, unusually, the facial bones, enough to permit a reasonably complete reconstruction. Larger than the skulls found in 1969 and 1970, this example had approximately twice the cranial capacity of *Australopithecus* and more than half that of a modern human—nearly 800 cubic centimeters. At the time, Leakey believed the fragments to be 2.9 million years old (although a more recent dating of the site would place them at less than 2 million years old). Basing his theory in part on these data, Leakey developed the view that these early hominids may have lived as early as 2.5 or even 3.5 million years ago and gave evidence to the theory that *Homo habilis* was not a descendant of the australopithecines, but a contemporary.

By the late 1960s, relations between Richard Leakey and his father had become strained, partly because of real or imagined competition within the administrative structure of the Centre for Prehistory, and partly because of some

divergences in methodology and interpretation. Shortly before Louis Leakey's death, however, the discovery of Skull 1470 by Richard Leakey's team allowed Richard to present his father with apparent corroboration of one of his central theories.

Richard Leakey did not make his theories of human evolution public until 1974. At this time, scientists were still grappling with Louis Leakey's interpretation of his findings that there had been at least two parallel lines of human evolution, only one of which led to modern humans. After Louis Leakey's death, Richard Leakey reported that, based on new finds, he believed that hominids diversified between 3 and 3.5 million years ago. Various lines of australopithecines and *Homo* coexisted, with only one line, *Homo,* surviving. The australopithecines and *Homo* shared a common ancestor; *Australopithecus* was not ancestral to *Homo.* As did his father, Leakey believes that *Homo* developed in Africa, and it was *Homo erectus* who, approximately 1.5 million years ago, developed the technological capacity to begin the spread of humans beyond their African origins. In Richard Leakey's scheme, *Homo habilis* developed into *Homo erectus*, who in turn developed into *Homo sapiens,* the present-day human.

As new finds are made, new questions arise. Are newly discovered variants proof of a plurality of species, or do they give evidence of greater variety within the species that have already been identified? To what extent is sexual dimorphism responsible for the apparent differences in the fossils? In some scientific circles, the discovery of fossil remains at Hadar in Ethiopia by archaeologist Donald Carl Johanson and others, along with the more recent revised dating of Skull 1470, cast some doubt on Leakey's theory in general and on his interpretation of *Homo habilis* in particular. Johanson believed that the fossils he found at Hadar and the fossils Mary Leakey found at Laetoli in Tanzania, and which she classified as *Homo habilis*, were actually all australopithecines; he termed them *Australopithecus afarensis* and claimed that this species is the common ancestor of both the later australopithecines and *Homo*. Richard Leakey has rejected this argument, contending that the australopithecines were not ancestral to *Homo* and that an earlier common ancestor would be found, possibly among the fossils found by Mary Leakey at Laetoli.

The year 1975 brought another significant find by Leakey's team at Koobi Fora: the team found what was apparently the skull of a *Homo erectus*, according to Louis Leakey's theory a descendent of *Homo habilis* and probably dating to 1.5 million years ago. This skull, labeled "3733," represents the earliest known evidence for *Homo erectus* in Africa.

Richard Leakey began to suffer from health problems during the 1970s, and in 1979 he was diagnosed with a serious kidney malfunction. Later that year he underwent a kidney transplant operation, his younger brother Philip being the donor. During his recuperation Richard completed his autobiography, *One Life*, which was released in 1984, and following his recovery, he renewed his search for the origins of the human species. The summer of 1984 brought another major discovery: the so-called Turkana boy, a nearly complete skeleton of a *Homo erectus*, missing little but the hands and feet, and offering, for the first time, the opportunity to view many bones of this species. It was shortly after the unearthing of Turkana boy—whose skeletal remains indicate that he was a twelve-year-old youngster who stood approximately five-and-a-half feet tall—that the puzzle of human evolution became even more complicated. The discovery of a new skull, called the Black Skull, with an *Australopithecus boisei* face but a cranium that was quite apelike, introduced yet another complication, possibly a fourth branch in the evolutionary tree. Leakey became the Director of the Wildlife **Conservation** and Management Department for Kenya (Kenya Wildlife Service) in 1989 and in 1999 became head of the Kenyan civil service.

Leaking underground storage tank

Leaking underground storage tanks (LUST) that hold toxic substances have come under new regulatory scrutiny in the United States because of the health and environmental hazards posed by the materials that can leak from them. These storage tanks typically hold **petroleum** products and other toxic **chemicals** beneath gas stations and other petroleum facilities. An estimated 63,000 of the nation's underground storage tanks have been shown to leak contaminants into the **environment** or are considered to have the potential to leak at any time. One reason for the instability of underground storage tanks is their construction. Only five percent of underground storage tanks are made of corrosion-protected steel, while 84 percent are made of bare steel, which corrodes easily. Another 11 percent of underground storage tanks are made of fiberglass.

Hazardous materials seeping from some of the nation's six million LUSTs can contaminate aquifers, the water-bearing rock units that supply much of the earth's drinking water. An **aquifer**, once contaminated, can be ruined as a source of fresh water. In particular, **benzene** has been found

to be a contaminant of **groundwater** as a result of leaks from underground **gasoline** storage tanks. Benzene and other volatile organic compounds have been detected in bottled water despite manufacturers' claims of purity.

According to the **Environmental Protection Agency** (EPA), more than 30 states reported groundwater contamination from petroleum products leaking from underground storage tanks. States also reported water contamination from **radioactive waste leaching** from storage containment facilities. Other reported **pollution** problems include leaking hazardous substances that are corrosive, explosive, readily flammable, or chemically reactive. While **water pollution** may be the most visible consequence of leaks from underground storage tanks, fires and explosions are dangerous and sometimes real possibilities in some areas.

The EPA is charged with exploring, developing, and disseminating technologies and funding mechanisms for cleanup. The primary job itself, however, is left to state and local governments. Actual cleanup is sometimes funded by the Leaking Underground Storage Tank trust fund established by Congress in 1986. Under the Superfund Amendment and Reauthorization Act, owners and operators of underground storage tanks are required to take corrective action to prevent leakage. *See also* Comprehensive Environmental Response, Compensation and Liability Act; Groundwater monitoring; Groundwater pollution; Storage and transport of hazardous materials; Toxic Substances Control Act

Aldo Leopold (1886 – 1978)

American conservationist, ecologist, and writer

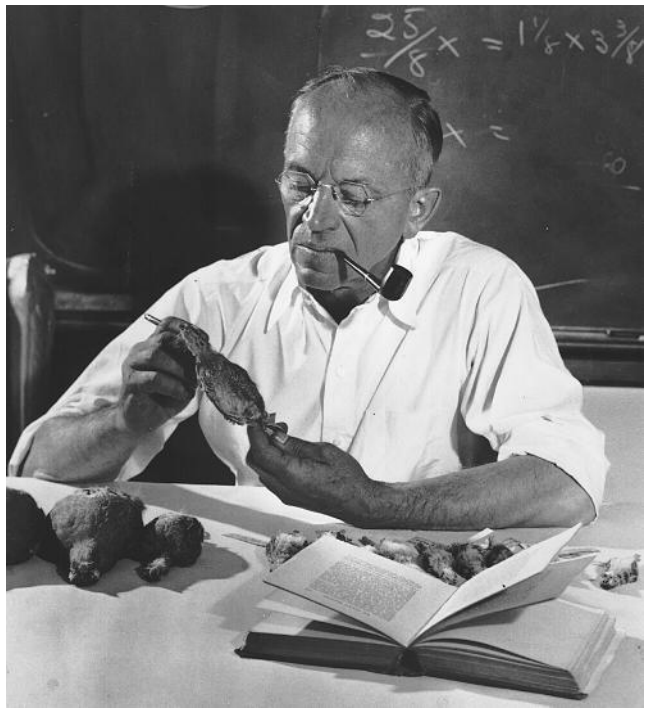
Leopold was a noted forester, game manager, conservationist, college professor, and ecologist. Yet he is known worldwide for *A Sand County Almanac*, a little book considered an important, influential work to **conservation** movement of the twentieth century. In it, Leopold established the **land ethic**, guidelines for respecting the land and preserving its integrity. Leopold grew up in Iowa, in a house overlooking the Mississippi River, where he learned **hunting** from his father and an appreciation of **nature** from his mother. He received a master's degree in forestry from Yale and spent his formative professional years working for the United States **Forest Service** in the American Southwest.

In the Southwest, Leopold began slowly to consider preservation as a supplement to Gifford Pinchot's "conservation as wise use—greatest good for the greatest number" land management philosophy that he learned at Yale and in the Forest Service. He began to formulate arguments for the preservation of **wilderness** and the **sustainable development** of wild game. Formerly a hunter who encouraged the elimination of predators to save the "good" animals for hunters, Leopold became a conservationist who remembered with sadness the "dying fire" in the eyes of a wolf he had killed. In the *Journal of Forestry*, he began to speculate that perhaps Pinchot's principle of highest use itself demanded "that representative portions of some forests be preserved as wilderness."

Leopold must be recognized as one of a handful of originators of the wilderness idea in American conservation history. He was instrumental in the founding of the **Wilderness Society** in 1935, which he described in the first issue of *Living Wilderness* as "one of the focal points of a new attitude—an intelligent humility toward man's place in nature." In a 1941 issue of that same journal, he asserted that wilderness also has critical practical uses "as a base-datum of normality, a picture of how healthy land maintains itself," and that wilderness was needed as a living "land laboratory."

This thinking led to the first large area designated as wilderness in the United States. In 1924, some 574,000 acres (232,000 ha) of the Gila **National Forest** in New Mexico was officially named a wilderness area. Four years before, the much smaller Trappers Lake valley in Colorado was the first area designated "to be kept roadless and undeveloped."

Aldo Leopold is also widely acknowledged as the founder of **wildlife management** in the United States. His classic text on the subject, *Game Management* (1933), is still in print and widely read. Leopold tried to write a general management framework, drawing upon and synthesizing **species** monographs and local manuals. "Details apply to game alone, but the principles are of general import to all fields of conservation," he wrote. He wanted to coordinate "science and use" in his book and felt strongly that land managers could either try to apply such principles, or be reduced to "hunting rabbits." Here can be found early uses of concepts still central to conservation and management, such as limiting factor, **niche**, saturation point, and **carrying capacity**. Leopold later became the first professor of game



management in the United States at the University of Wisconsin.

Leopold's *A Sand County Almanac*, published in 1949, a year after his death, is often described as "the bible of the environmental movement" of the second half of the twentieth century. The *Almanac* is a beautifully written source of solid ecological concepts such as trophic linkages and **biological community**. The book extends basic ecological concepts, forming radical ideas to reformulate human thinking and behavior. It exhibits an ecological conscience, a conservation aesthetic, and a land ethic. He advocated his concept of ecological conscience to fill in a perceived gap in conservation education: "Obligations have no meaning without conscience, and the problem we face is the extension of the social conscience from people to land." Lesser known is his attention to the aesthetics of land: according to the *Almanac*, an acceptable land aesthetic emerges only from learned and sensitive perception of the connections and needs of natural communities. The last words in the *Almanac* are that a true conservation aesthetic is developed "not of building roads into lovely country, but of building receptivity into the still unlovely human mind."

Leopold derived his now famous land ethic from an ecological conception of community. All ethics, he maintained, "rest upon a single premise: that the individual is a member of a community of interdependent parts." He argued that "the land ethic simply enlarges the boundaries of the community to include soils, waters, plants, and animals, or collectively: the land." Perhaps the most widely quoted statement from the book argues that "a thing is right when it tends to preserve the integrity, **stability**, and beauty of the **biotic community**. It is wrong when it tends otherwise."

Leopold's land ethic was first proposed in the *Journal of Forestry* article in 1933 and later expanded in the *Almanac*. It is a plea to care for land and its biological complex, instead of considering it a commodity. As Wallace Tegner noted, Leopold's ideas were heretical in 1949, and to some people still are. "They smack of socialism and the public good," he wrote. "They impose limits and restraints. They are anti-Progress. They dampen American initiative. They fly in the face of the faith that land is a commodity, the very foundation stone of American opportunity." As a result, Stegner and others do not think Leopold's ethic had much influence on public thought, though the book has been widely read. Leopold recognized this. "The case for a land ethic would appear hopeless but for the minority which is in obvious revolt against these 'modern' trends," he commented. Nevertheless, the land ethic is alive and still flourishing, in an ever-growing minority. Even Stegner argued that "Leopold's land ethic is not a fact but [an on-going] task." Leopold did not shrink from that task, being actively involved in many conservation associations, teaching management principles and the land ethic to his classes, bringing up all five of his children to become conservationists, and applying his beliefs directly to his own land, a parcel of "logged, fire-swept, overgrazed, barren" land in Sauk County, Wisconsin. As his work has become more recognized and more influential, many labels have been applied to Leopold by contemporary writers. He is a "prophet" and "intellectual touchstone" to Roderick Nash a "founding genius" to J. Baird Callicott "an American Isaiah" to Stegner the "Moses of the new conservation impulse" to Donald Fleming. In a sense, he may have been all of these, but more than anything else, Leopold was an applied ecologist who tried to put into practice the principles he learned from the land.

Less developed countries

Less developed countries (LDCs) have lower levels of economic prosperity, health care, and education than most other countries. Development or improvement in economic and social conditions encompasses various aspects of general welfare, including infant survival, expected life span, nutrition, literacy rates, employment, and access to material goods. Less developed countries (LDCs) are identified by their relatively poor ratings in these categories. In addition, most LDCs are marked by high **population growth**, rapidly expanding cities, low levels of technological development, and weak economies dominated by agriculture and the export of **natural resources**. Because of their limited economic and technological development, LDCs tend to have relatively little international political power compared to more developed countries (MDC) such as Japan, the United States, and Germany.

A variety of standard measures, or development indices, are used to assess development stages. These indices are generalized statistical measures of quality of life for individuals in a society. Multiple indices are usually considered more accurate than a single number such as Gross National Product, because such figures tend to give imprecise and simplistic impressions of conditions in a country. One of the most important of the multiple indices is the infant **mortality** rate. Because children under five years old are highly susceptible to common diseases, especially when they are malnourished, infant mortality is a key to assessing both nutrition and access to health care. Expected life span, the average age adults are able to reach, is used as a measure of adult health. Daily calorie and protein intake per person are collective measures that reflect the ability of individuals to grow and function effectively. Literacy rates, especially among women, who are normally the last to receive an education, indicate access to schools and preparation for technologically advanced employment.

Fertility rates are a measure of the number of children produced per family or per woman in a population and are regarded as an important measure of the confidence parents have in their childrens' survival. High birth rates are associated with unstable social conditions because a country with a rapidly growing population often cannot provide its citizens with food, water, **sanitation**, housing space, jobs, and other basic needs. Rapidly growing populations also tend to undergo rapid urbanization. People move to cities in search of jobs and educational opportunities, but in poor countries the cost of providing basic infrastructure in an expanding city can be debilitating. As most countries develop, they pass from a stage of high birth rates to one of low birth rates, as child survival becomes more certain and a family's investment in educating and providing for each child increases.

Most LDCs were colonies under foreign control during the past 200 years. Colonial powers tended to undermine social organization, local economies, and natural resource bases, and many recently independent states are still recovering from this legacy. Thus, much of Africa, which provided a wealth of natural resources to Europe between the seventeenth and twentieth centuries, now lacks the effective and equitable social organization necessary for continuing development. Similarly, much of Central America (colonized by Spain in the fifteenth century) and portions of South and Southeast Asia (colonized by England, France, the Netherlands, and others) remain less developed despite their wealth of natural resources. The development processes necessary to improve standards of living in LDCs may involve more natural resource extraction, but usually the most important steps involve carefully choosing the goods to be produced, decreasing corruption among government and business leaders, and easing the social unrest and conflicts that prevent development from proceeding. All of these are extraordinarily difficult to do, but they are essential for countries trying to escape from poverty. *See also* Child survival revolution; Debt for nature swap; Economic growth and the environment; Indigenous peoples; Shanty towns; South; Sustainable development; Third World; Third World pollution; Tropical rain forest; World Bank

Leukemia

Leukemia is a disease of the blood-forming organs. Primary tumors are found in the bone marrow and lymphoid tissues,

specifically the liver, spleen, and lymph nodes. The characteristic common to all types of leukemia is the uncontrolled proliferation of leukocytes (white blood cells) in the blood stream. This results in a lack of normal bone marrow growth, and bone marrow is replaced by immature and undifferentiated leukocytes or "blast cells." These immature and undifferentiated cells then migrate to various organs in the body, resulting in the pathogenesis of normal organ development and processing.

Leukemia occurs with varying frequencies at different ages, but it is most frequent among the elderly who experience 27,000 cases a year in the United States to 2,200 cases a year for younger people. Acute lymphoblastic leukemia, most common in children, is responsible for two-thirds of all cases. Acute nonlymphoblastic leukemia and chronic lymphocytic leukemia are most common among adults—they are responsible for 8,000 and 9,600 cases a year respectively. The geographical sites of highest concentration are the United States, Canada, Sweden, and New Zealand. While there is clear evidence that some leukemias are linked to genetic traits, the origins of this disease in most cases is mysterious. It seems clear, however, that environmental exposure to radiation, toxic substances, and other risk factors plays an important role in many leukemias. *See also* Cancer; Carcinogen; Radiation exposure; Radiation sickness

Lichens

Lichens are composed of **fungi** and algae. Varying in color from pale whitish green to brilliant red and orange, lichens usually grow attached to rocks and tree trunks and appear as thin, crusty coatings, as networks of small, branched strands, or as flattened, leaf-like forms. Some common lichens are reindeer moss and the red "British soldiers." There are approximately 20,000 known lichen **species**. Because they often grow under cold, dry, inhospitable conditions, they are usually the first plants to colonize barren rock surfaces.

The fungus and the alga form a symbiotic relationship within the lichen. The fungus forms the body of the lichen, called the thallus. The thallus attaches itself to the surface of a rock or tree trunk, and the fungal cells take up water and nutrients from the **environment**. The algal cells grow inside the fungal cells and perform **photosynthesis**, as do other plant cells, to form carbohydrates.

Lichens are essential in providing food for other organisms, breaking down rocks, and initiating **soil** building. They are also important indicators and monitors of **air pollution** effects. Since lichens grow attached to rock and tree surfaces, they are fully exposed to airborne pollutants, and chemical analysis of lichen tissues can be used to measure the quantity of pollutants in a particular area. For example, **sulfur dioxide**, a common **emission** from **power plants**, is a major air pollutant. Many studies show that as the concentrations of sulfur dioxide in the air increase, the number of lichen species decreases. The disappearance of lichens from an area may be indicative of other, widespread biological impacts.

Sometimes, lichens are the first organisms to transfer contaminants to the food chain. Lichens are abundant through vast regions of the arctic **tundra** and form the main food source for caribou (*Rangifer tarandus*) in winter. The caribou are hunted and eaten by northern Alaskan Eskimos in spring and early summer. When the effects of **radioactive fallout** from weapons-testing in the arctic tundra were studied, it was discovered that lichens absorbed virtually all of the **radionuclides** that were deposited on them. Strontium-90 and cesium-137 were two of the major radionuclide contaminants. As caribou grazed on the lichens, these radionuclides were absorbed into the caribous' tissues. At the end of the winter, caribou flesh contained three to six times as much cesium-137 as it did in the fall. When the caribou flesh was consumed by the Eskimos, the radionuclides were transferred to them as well. *See also* Indicator organism; Symbiosis

Life cycle assessment

Life cycle assessment (or LCA) refers to a process in industrial **ecology** by which the products, processes, and facilities used to manufacture specific products are each examined for their environmental impacts. A balance sheet is prepared for each product that considers: the use of materials; the consumption of energy; the **recycling**, re-use, and/or disposal of non-used materials and energy (in a less-enlightened context, these are referred to as "wastes"); and the recycling or re-use of products after their commercial life has passed. By taking a comprehensive, integrated look at all of these aspects of the manufacturing and use of products, life cycle assessment finds ways to increase efficiency, to re-use, reduce, and recycle materials, and to lessen the overall environmental impacts of the process.

Limits to Growth (1972) and *Beyond the Limits* (1992)

Published at the height of the oil crisis in the 1970s, the *Limits to Growth* study is credited with lifting environmental concerns to an international and global level. Its fundamental conclusion is that if rapid growth continues unabated in the five key areas of population, food production, industrialization, **pollution**, and consumption of nonrenewable **natural resources**, the planet will reach the limits of growth within 100 years. The most probable result will be a "rather sudden and uncontrollable decline in both population and industrial capacity."

The study grew out of an April 1968 meeting of 30 scientists, educators, economists, humanists, industrialists, and national and international civil servants who had been brought together by Dr. Aurelio Peccei, an Italian industrial manager and economist. Peccei and the others met at the Accademia dei Lincei in Rome to discuss the "present and future predicament of man," and from their meeting came the **Club of Rome**. Early meetings of the club resulted in a decision to initiate the Project on the Predicament of Mankind, intended to examine the array of problems facing all nations. Those problems ranged from poverty amidst plenty and **environmental degradation** to the rejection of traditional values and various economic disturbances.

In the summer of 1970, Phase One of the project took shape during a series of meetings in Bern, Switzerland and Cambridge, Massachusetts. At a two-week meeting in Cambridge, Professor Jay Forrester of the Massachusetts Institute of Technology (MIT) presented a global model for analyzing the interacting components of world problems. Professor Dennis Meadows led an international team in examining the five basic components, mentioned above, that determine growth on this planet and its ultimate limits. The team's research culminated in the 1972 publication of the study, which touched off intense controversy and further research.

Underlying the study's dramatic conclusions is the central concept of **exponential growth**, which occurs when a quantity increases by a constant percentage of the whole in a constant time period. "For instance, a colony of yeast cells in which each cell divides into two cells every ten minutes is growing exponentially," the study explains. The model used to capture the dynamic quality of exponential growth is a System Dynamics model, developed over a 30-year period at MIT, which recognizes that the structure of any system determines its behavior as much as any individual parts of the system. The components of a system are described as "circular, interlocking, sometimes time-delayed." Using this model (called World3), the study ran scenarios—what-if analyses—to reach its view of how the world will evolve if present trends persist.

"Dynamic **modeling** theory indicates that any exponentially growing quantity is somehow involved with a positive feedback loop," the study points out. "In a positive feedback loop a chain of cause-and-effect relationships closes on itself, so that increasing any one element in the loop will start a sequence of changes that will result in the originally changed element being increased even more."

In the case of world **population growth**, the births per year act as a positive feedback loop. For instance, in 1650, world population was half a billion and was growing at a rate of 0.3 percent a year. In 1970, world population was 3.6 billion and was growing at a rate of 2.1 percent a year. Both the population and the rate of population growth have been increasing exponentially. But in addition to births per year, the dynamic system of population growth includes a negative feedback loop: deaths per year. Positive feedback loops create runaway growth, while negative feedback loops regulate growth and hold a system in a stable state. For instance, a thermostat will regulate temperature when a room reaches a certain temperature, the thermostat shuts off the system until the temperature decreases enough to restart the system. With population growth, both the birth and death rates were relatively high and irregular before the Industrial Revolution. But with the spread of medicines and longer life expectancies, the death rate has slowed while the birth rate has risen. Given these trends, the study predicted a worldwide jump in population of seven billion over 30 years.

This same dynamic of positive and negative feedback loops applies to the other components of the world system. The growth in world industrial capital, with the positive input of investment, creates rising industrial output, such as houses, automobiles, textiles, consumer goods, and other products. On the negative feedback side, depreciation, or the capital discarded each year, draws down the level of industrial capital. This feedback is "exactly analogous to the death rate loop in the population system," the study notes. And, as with world population, the positive feedback loop is "strongly dominant," creating steady growth in worldwide industrial capital and the use of raw materials needed to create products.

This system in which exponential growth is occurring, with positive feedback loops outstripping negative ones, will push the world to the limits of exponential growth. The study asks what will be needed to sustain world economic and population growth until and beyond the year 2000 and concludes that two main categories of ingredients can be

defined. First, there are physical necessities that support all physiological and industrial activity: food, raw materials, fossil and nuclear fuels, and the ecological systems of the planet that absorb waste and recycle important chemical substances. **Arable land**, fresh water, metals, forests, and oceans are needed to obtain those necessities. Second, there are social necessities needed to sustain growth, including peace, social **stability**, education, employment, and steady technological progress.

Even assuming that the best possible social conditions exist for the promotion of growth, the earth is finite and therefore continued exponential growth will reach the limits of each physical necessity. For instance, about 1 acre (0.4 ha) of arable land is needed to grow enough food per person. With that need for arable land, even if all the world's arable land were cultivated, current population growth rates will still create a "desperate land shortage before the year 2000," the study concludes. The availability of fresh water is another crucial limiting factor, the study points out. "There is an upper limit to the fresh water **runoff** from the land areas of the earth each year, and there is also an exponentially increasing demand for that water."

This same analysis is applied to **nonrenewable resources**, such as metals, **coal**, iron, and other necessities for industrial growth. World demand is rising steadily and at some point demand for each nonrenewable resource will exceed supply, even with **recycling** of these materials. For instance, the study predicts that even if 100 percent recycling of chromium from 1970 onward were possible, demand would exceed supply in 235 years. Similarly, while it is not known how much pollution the world can take before vital natural processes are disrupted, the study cautions that the danger of reaching those limits is especially great because there is usually a long delay between the time a pollutant is released and the time it begins to negatively affect the **environment**.

While the study foretells worldwide collapse if exponential growth trends continue, it also argues that the necessary steps to avert disaster are known and are well within human capabilities. Current knowledge and resources could guide the world to a sustainable equilibrium society provided that a realistic, long-term goal and the will to achieve that goal are pursued.

The sequel to the 1972 study, *Beyond the Limits*, was not sponsored by the Club of Rome, but it is written by three of the original authors. While the basic analytical framework remains the same in the later work—drawing upon the concepts of exponential growth and feedback loops to describe the world system—its conclusions are more severe. No longer does the world only face a potential of "overshooting" its limits. "Human use of many essential resources and generation of many kinds of pollutants have already surpassed rates that are physically sustainable," according to the 1992 study. "Without significant reductions in material and energy flows, there will be in the coming decades an uncontrolled decline in per capita food output, energy use, and industrial output."

However, like its predecessor, the later study sounds a note of hope, arguing that decline is not inevitable. To avoid disaster requires comprehensive reforms in policies and practices that perpetuate growth in material consumption and population. It also requires a rapid, drastic jump in the efficiency with which we use materials and energy.

Both the earlier and the later study were received with great controversy. For instance, economists and industrialists charged that the earlier study ignored the fact that technological innovation could stretch the limits to growth through greater efficiency and diminishing pollution levels. When the sequel was published, some critics charged that the World3 model could have been refined to include more realistic distinctions between nations and regions, rather than looking at all trends on a world scale. For instance, different continents, rich and poor nations, North, South, and East, various regions—all are different, but those differences are ignored in the model, thereby making it unrealistic even though modeling techniques have evolved significantly since World3 was first developed. *See also* Sustainable development

Limnology

Derived from the Greek word *limne*, meaning marsh or pond, the term limnology was first used in reference to lakes by F. A. Forel (1841–1912) in 1892 in a paper titled "Le Léman: Monographie Limnology," a study of what we now call Lake Geneva in Switzerland. Limnology, also known as aquatic **ecology**, refers to the study of fresh water communities within continental boundaries. It can be subdivided into the study of lentic (standing water habitats such as lakes, ponds, bogs, swamps, and marshes) and lotic (running water habitats such as rivers, streams, and brooks) environments. Collectively, limnologists study the morphological, physical, chemical, and biological aspects of these habitats.

Raymond L. Lindeman (1915 – 1942)

American ecologist

Few scholars or scientists, even those much published and long-lived, leave singular, indelible imprints on their disciplines,. Yet, Raymond Lindeman, in 26 short years, who published just six articles, was described shortly after his death by G. E. Hutchinson as "one of the most creative and generous minds yet to devote itself to ecological science," and the last of those six papers, "The Trophic-Dynamic Aspect of Ecology,"—published posthumously in 1942—continues to be considered one of the foundational papers in **ecology**, an article "path-breaking in its general analysis of ecological **succession** in terms of **energy flow** through the ecosystem," an article based on an idea that Edward Kormondy has called "the most significant formulation in the development of modern ecology."

Immediately after completing his doctorate at the University of Minnesota, Lindeman accepted a one-year Sterling fellowship at Yale University to work with G. Evelyn Hutchinson, the Dean of American limnologists. He had published chapters of his thesis one by one and at Yale worked to revise the final chapter, refining it with ideas drawn from Hutchinson's lecture notes and from their discussions about the ecology of lakes. Lindeman submitted the manuscript to Ecology with Hutchinson's blessings, but it was rejected based on reviewers' claims that it was speculation far beyond the data presented from research on three lakes, including Lindeman's own doctoral research on Cedar Bog Lake. After input from several well-known ecologists, further revisions, and with further urging from Hutchinson, the editor finally overrode the reviewers' comments and accepted the manuscript; it was published in the October, 1942 issue of *Ecology*, a few months after Lindeman died in June of that year.

The important advances made by Lindeman's seminal article included his use of the **ecosystem** concept, which he was convinced was "of fundamental importance in interpreting the data of dynamic ecology," and his explication of the idea that "all function, and indeed all life" within ecosystems depends on the movement of energy through such systems by way of trophic relationships. His use of ecosystem went beyond the little attention paid to it by Hutchinson and beyond Tansley's labeling of the unit seven years earlier to open up "new directions for the analysis of the functioning of ecosystems." More than half a century after Lindeman's article, and despite recent revelations on the uncertainty and unpredictability of natural systems, a majority of ecologists probably still accept ecosystem as the basic unit in ecology and, in those systems, energy exchange as the basic process.

Lindeman was able to effectively demonstrate a way to bring together or synthesize two quite separate traditions in ecology, **autecology**, dependent on physiological studies of individual organisms and **species**, and synecology focused on studies of communities, aggregates of individuals. He believed, and demonstrated, that ecological research would benefit from a synthesis of these organism-based approaches and focus on the energy relationships that tied organism and **environment** into one unit—the ecosystem—suggesting as a result that biotic and abiotic could not realistically be disengaged, especially in ecology.

Half a decade or so of work on cedar bog lakes, and half a dozen articles would seem a thin stem on which to base a legacy. But it really boils down to Lindeman's synthesis of that work in that one singular, seminal paper, in which he created one of the significant stepping stones from a mostly descriptive discipline toward a more sophisticated and modern theoretical ecology.

Liquid metal fast breeder reactor

The liquid metal fast breeder reactor (LMFBR) is a nuclear reactor that has been modified to increase the efficiency at which non-fissionable uranium-238 is converted to fissionable plutonium-239, which can be used as fuel in the production of **nuclear power**. The reactor uses "fast" rather than "slow" neutrons to strike a uranium-238 nucleus, resulting in the formation of plutonium-239. In a second modification, it uses a liquid metal, usually sodium, rather than neutron-absorbing water as a more efficient coolant. Since the reactor produces new fuel as it operates, it is called a breeder reactor.

The main appeal of breeder reactors is that they provide an alternative way of obtaining fissionable materials. The supply of natural **uranium** in the earth's crust is fairly large, but it will not last forever. Plutonium-239 from breeder reactors might become the major fuel used in reactors built a few hundred or thousand years from now.

However, the potential of LMFBRs has not as yet been realized. One serious problem involves the use of liquid sodium as coolant. Sodium is a highly corrosive metal and in an LMFBR it is converted into a radioactive form, sodium-24. Accidental release of the coolant from such a plant could, therefore, constitute a serious environmental hazard.

Liquid metal fast breeder reactor. (McGraw-Hill Inc. Reproduced by permission.)

In addition, **plutonium** itself is difficult to work with. It is one of the most toxic substances known to humans, and its **half-life** of 24,000 years means that its release presents long-term environmental problems.

Small-scale pilot LMFBR reactors have been tested in the United States, Saudi Arabia, Great Britain, and Germany since 1966, and all have turned out to be far more expensive than had been anticipated. The major United States research program based at Clinch, Tennessee, began in 1970. By 1983, the U. S. Congress refused to continue funding the project due to its slow and unsatisfactory progress. *See also* Nuclear fission; Nuclear Regulatory Commission; Radioactivity; Radioactive waste management

Liquified natural gas

Natural gas is a highly desirable fuel in many respects. It burns with the release of a large amount of energy, producing almost entirely **carbon dioxide** and water as waste products. Except for possible greenhouse effects of **carbon** dioxide, these compounds produce virtually no environmental hazard. Transporting natural gas through transcontinental pipelines is inexpensive and efficient where **topography** allows the laying of pipes. Oceanic shipping is difficult, however, because of the flammability of the gas and the high volumes involved. The most common way of dealing with these problems is to condense the gas first and then transport it in the form of liquified natural gas (LNG). But LNG must be maintained at temperatures of about -260°F (-160°C) and protected from leaks and flames during **loading** and unloading. *See also* Fossil fuels

Lithology

Lithology is the study of rocks, emphasizing their macroscopic physical characteristics, including grain size, mineral composition, and color. Lithology and its related field, petrography (the description and systematic classification of rocks), are subdisciplines of petrology, which also considers microscopic and chemical properties of minerals and rocks as well as their origin and decay.

Littoral zone

In marine systems, littoral zone is synonymous with intertidal zone and refers to the area on marine shores that is periodically exposed to air during low tide. The freshwater littoral zone is that area near the shore characterized by submerged, floating, or emergent vegetation. The width of a particular littoral zone may vary from several miles to a few feet. These areas typically support an abundance of organisms and are important feeding and nursery areas for fishes, crustaceans, and birds. The distribution and abundance of individual **species** in the littoral zone is dependent on predation and **competition** as well as tolerance of physical factors. *See also* Neritic zone; Pelagic zone

Loading

The term loading has a wide variety of specialized meanings in various fields of science. In general, all refer to the addition of something to a system, just as loading a truck means filling it with objects. In the science of acoustics, for example, loading refers to the process of adding materials to a speaker in order to improve its acoustical qualities. In **environmental science**, loading is used to describe the contribution made to any system by some component. One might analyze, for example, how an increase in chlorofluorocarbon (CFC) loading in the **stratosphere** might affect the concentration of **ozone** there.

Logging

Logging is the systematic process of cutting down trees for lumber and wood products. The method of logging called clearcutting, in which entire areas of forests are cleared, is the most prevalent practice used by lumber companies. Clearcutting is the cheapest and most efficient way to harvest a forest's available resources. This practice drastically alters the forest **ecosystem**, and many plants and animals are displaced or destroyed by it. After clearcutting is performed on forests, forestry management techniques may be introduced in order to manage the growth of new trees on the cleared land. Selective logging is an alternative to clearcutting. In selective logging, only certain trees in a forest are chosen to be logged, usually on the basis of their size or **species**. By taking a smaller percentage of trees, the forest is protected from destruction and fragile plants and animals in the forest ecosystem are more likely to survive. New, innovative techniques offer alternatives for preserving the forest. For example, the Shelterwood Silvicultural System harvests mature trees in phases. First, part of the original stand is removed to promote growth of the remaining trees. After this occurs, regeneration naturally follows using seeds provided by the remaining trees. Once regeneration has occurred, the remaining mature trees are harvested.

Early logging equipment included long, two-man straight saws and teams of animals to drag trees away. After World War II, technological advances made logging easier. The bulldozer and the helicopter allowed loggers to enter into new and previously untouched areas. The chainsaw allowed loggers to cut down many more trees each day. Today, enormous machines known as feller-bunchers take the place of human loggers. These machines use a hydraulic clamp that grasps the individual tree and huge shears that cut through it in one swift motion.

High demands for lumber and forest products have caused prolific and widespread commercial logging. Certain methods of timber harvesting allow for subsequent regeneration, while others cause **deforestation**, or the irreversible creation of a non-forest condition. Deforestation significantly changed the landscape of the United States. Some observers remarked as early as the mid-1700s upon the rapid changes made to the forests from the East Coast to the Ohio River Valley. Often, the lumber in forests was burned away so that the early settlers could build farms upon the rich **soil** that had been created by the forest ecosystem. The immediate results of deforestation are major changes to Earth's landscapes and diminishing **wildlife** habitats. Longer-range results of deforestation, including unrestrained commercial logging, may include damage to Earth's **atmosphere** and the unbalancing of living ecosystems. Forests help to remove **carbon dioxide** from the air. Through the process of **photosynthesis**, forests release oxygen into the air. A single acre of temperate forest releases more than six tons of oxygen into the atmosphere every year. In the last 150 years, deforestation, together with the burning of **fossil fuels**, has raised the amount of **carbon** dioxide in the atmosphere by more than 25%. It has been theorized that this has contributed to global warming, which is the accumulation of gasses leading to a gradual increase in Earth's surface temperature. Human beings are still learning how to measure their need for wood against their need for a viable **environment** for themselves and other life forms.

Although human activity, especially logging, has decimated many of the world's forests and the life within them, some untouched forests still remain. These forests are known as old-growth or ancient-growth forests. Old-growth forests are at the center of a heated debate between environmentalists, who wish to preserve them, and the logging industry, which continually seeks new and profitable sources of lumber and other forest products.

Very little of the original uncut North American forest still remains. It has been estimated that the United States has lost over 96% of its old-growth forests. This loss continues as logging companies become more attracted to ancient-growth forests, which contain larger, more profitable trees. A majority of old-growth forests in the United States are in Alaska and Pacific Northwest. On the global level, barely 20% of the old-growth forests still remain, and the South American rainforests account for a significant portion of these. About 1% of the Amazon rainforest is deforested each year. At the present rate of logging around the world, old-growth forests could be gone within the first few decades of the twenty-first century unless effective **conservation** programs are instituted.

As technological advancements of the twentieth century dramatically increased the efficiency of logging, there was also a growth in understanding about the contribution of the forest to the overall health of the environment, including the effect of logging upon that health. Ecologists, who are scientists that study the complex relationships within natural systems, have determined that logging can affect the health of air, soil, water, plant life, and animals. For instance, clearcutting was at one time considered a healthy forestry practice, as proponents claimed that clearing a forest enabled the growth of new plant life, sped the process of regeneration, and prevented fires. The American Forest Institute, an industry group, ran an ad in the 1970s that stated, "I'm clearcutting to save the forest." Ecologists have come to understand that clearcutting old-growth forests has a devastating effect on plant and animal life, and affects the health of the forest ecosystem from its rivers to its soil. Old-growth trees, for example, provide an ecologically diverse **habitat** including woody debris and **fungi** that contribute to nutrient-rich soil. Furthermore, many species of plants and wildlife, some still undiscovered, are dependent upon old-growth forests for survival. The huge canopies created by old-growth trees protect the ground from water **erosion** when it rains, and their roots help to hold the soil together. This in turn maintains the health of rivers and streams, upon which fish and other aquatic life depend. In the Pacific Northwest, for example, ecologists have connected the health of the **salmon** population with the health of the forests and the logging practices therein. Ecologists now understand that clearcutting and the planting of new trees, no matter how scientifically managed, cannot replace the wealth of **biodiversity** maintained by old-growth forests.

The pace of logging is dictated by the consumer demand for lumber and wood products. In the United States, for instance, the average size of new homes doubled between 1970 and 2000, and the forests ultimately bear the burden of the increasing consumption of lumber. In the face of widespread logging, environmentalists have become more desperate to protect ancient forests. There is a history of controversy between the timber industry and environmentalists regarding the relationship between logging and the care of forests. On the one hand, the logging industry has seen forests as a source of wealth, economic growth, and jobs. On the other hand, environmentalists have viewed these same forests as a source of **recreation**, spiritual renewal, and as living systems that maintain the overall **environmental health**. In the 1980s, a controversy raged between environmentalists and the logging industry over the protection of the **northern spotted owl**, a threatened species of bird whose habitat is the **old-growth forest** of the Pacific Northwest. Environmentalists appealed to the **Endangered Species Act** of 1973 to protect some of these old-growth forests. In other logging controversies, some environmentalists chained themselves to old-growth trees to prevent their destruction, and one activist, Julia Butterfly Hill, lived in an old-growth California redwood tree for two years in the 1990s to prevent it from being cut down. The clash between environmentalists and the logging industry may become more intense as the demand for wood increases and supplies decrease. However, in recent years these opposing views have been tempered by discussion of concepts such as responsible **forest management** to create sustainable growth, in combination with preservation of protected areas.

Most of the logging in the United States occurs in the national forests. From the point of view of the U.S. **Forest Service**, logging provides jobs, helps manage the forest in some respects, prevents logging in other parts of the world, and helps eliminate the danger of forest fires. To meet the demands of the logging industry, the national forests have been developed with a labyrinth of logging roads and contain vast areas that have been devastated by clearcutting. In the United States there are enough logging roads in the National Forests to circle the earth 15 times, roads that speed up soil erosion that then washes away fertile **topsoil** and pollutes streams and rivers.

The Roadless Initiative was established in 2001 to protect 60 million acres (24 million ha) of national forests. The initiative was designed by the Clinton administration to discourage logging and taxpayer-supported road building on public lands. The goal was to establish total and permanent protection for designated roadless areas. Advocates of the initiative contended that roadless areas encompassed

some of the best wildlife habitats in the nation, while forest service officials argued that banning road building would significantly reduce logging in these areas. Under the initiative, more than half of the 192 million acres (78 million ha) of **national forest** would still remain available for logging and other activities. This initiative was considered one of the most important environmental protection measures of the Clinton administration.

Illegal logging has become a problem with the growing worldwide demand for lumber. For example, the **World Bank** predicted that if Indonesia does not halt all current logging, it would lose its entire forest within the next 10 to 15 years. Estimates indicate that up to 70% of the wood harvested in Indonesia comes from illegal logging practices. Much of the timber being taken is sent to the United States. **Indigenous peoples** of Indonesia are being displaced from their traditional territories. Wildlife, including endangered **tigers**, **elephants**, rhinos, and orangutans are also being displaced and may be threatened with **extinction**. In 2002 Indonesia placed a temporary moratorium on logging in an effort to stop illegal logging.

Other countries around the world were addressing logging issues in the early twenty-first century. In China, 160 million acres (65 million ha) out of 618 million acres (250 million ha) were put under state protection. Loggers turned in their tools to become forest rangers, working for the government in order to safeguard trees from illegal logging. China has set aside millions of acres of forests for protection, particularly those forests that are crucial sources of fresh water. China also announced that it was planning to further reduce its timber output in order to restore and enhance the life-sustaining abilities of its forests.

Logistic growth

Assuming the rate of immigration is the same as emigration, population size increases when births exceed deaths. As population size increases, population density increases, and the supply of limited available resources per organism decreases. There is thus less food and less space available for each individual. As food, water, and space decline, fewer births or more deaths may occur, and this imbalance continues until the number of births are equal to the number of deaths at a population size that can be sustained by the available resources. This equilibrium level is called the **carrying capacity** for that **environment**.

A temporary and rapid increase in population may be due to a period of optimum growth conditions including physical and biological factors. Such an increase may push a population beyond the environmental carrying capacity. This sudden burst will be followed by a decline, and the population will maintain a steady fluctuation around the carrying capacity. Other population controls, such as predators and weather extremes (**drought**, frost, and floods), keep populations below the carrying capacity. Some environmentalists believe that the human population has exceeded the earth's carrying capacity.

Logistic growth, then, refers to growth rates that are regulated by internal and external factors that establish an equilibrium with **environmental resources**. The sigmoid (idealized S-shaped) curve illustrates this logistic growth where environmental factors limit **population growth**. In this model, a low-density population begins to grow slowly, then goes through an exponential or geometric phase, and then levels off at the environmental carrying capacity. *See also* Exponential growth; Growth limiting factors; Sustainable development; Zero population growth

Dr. Bjørn Lomborg (1965 –)

Danish political scientist

In 2001, Cambridge University Press published *The Skeptical Environmentalist: Measuring the Real State of the World* by

the Danish statistician Bjørn Lomborg. The book triggered a firestorm of criticism, with many well-known scientists denouncing it as an effort to "confuse legislators and regulators, and poison the well of public environmental information." In January 2002, *Scientific American* published a series of articles by five distinguished environmental scientists contesting Lomborg's claims. To some observers, the ferocity of the attack was surprising. Why so much furor over a book that claims to have good news about our environmental condition?

Lomborg portrays himself as an "left-wing, vegetarian, **Greenpeace** member," but says he worries about the unrelenting "doom and gloom" of mainstream **environmentalism**. He describes what he regards as an all-pervasive ideology that says, among other things, "Our resources are running out. The population is ever growing, leaving less and less to eat. The air and water are becoming ever more polluted. The planet's **species** are becoming extinct in vast numbers. The forests are disappearing, fish stocks are collapsing, and coral reefs are dying." This ideology has pervaded the environmental debate so long, Lomborg says, "that blatantly false claims can be made again and again, without any references, and yet still be believed."

In fact, Lomborg tells us, these allegations of the collapse of ecosystems are "simply not in keeping with reality. We are not running out of energy or **natural resources**. There will be more and more food per head of the world's population. Fewer and fewer people are starving. In 1900 we lived for an average of 30 years; today we live 67. According to the UN we have reduced poverty more in the last 50 years than in the preceding 500, and it has been reduced in practically every country." He goes on to challenge conventional scientific assessment of global warming, forest losses, fresh water **scarcity**, energy shortages, and a host of other environmental problems. Is Lomborg being deliberately (and some would say, hypocritically) optimistic, or are others being unreasonably pessimistic? Is this simply a case of regarding the glass as half full versus half empty?

The inspiration to look at environmental **statistics**, Lomborg says, was a 1997 interview with the controversial economist Dr. Julian L. Simon in *Wired* magazine. Simon, who died in 1998, spent a good share of his career arguing that the "litany" of the Green movement—human overpopulation leading to starvation and resource shortages—was premeditated hyperbole and fear mongering. The truth, Simon, claimed is that the quality of human life is improving, not declining.

Lomborg felt sure that Simon's allegations were "simple American right-wing propaganda." It should be a simple matter, he thought, to gather evidence to show how wrong Simon was. Back at his university in Denmark, Lomborg set out with 10 of his sharpest students to study Simon's claims. To their surprise, the group found that while not everything Simon said was correct, his basic conclusions seemed sound. When Lomborg began to publish these findings in a series of newspaper articles in the *London Guardian* in 1998, he stirred up a hornet's nest. Some of his colleagues at the University of Aarhus set up a website to denounce the work. When the whole book came out, their fury only escalated. Altogether, between 1998 and 2002, more than 400 articles appeared in newspapers and popular magazines either attacking or defending Lomborg and his conclusions.

In general, the debate divides between mostly conservative supporters on one side and progressive, environmental activists and scientists on the other. The *Wall Street Journal* described the *Skeptical Environmentalist* as "superbly documented and readable." *The Economist* called it "a triumph." A review in the *Daily Telegraph* (London) declared it "the most important book on the **environment** ever written." A review in the *Washington Post* said it is a "richly informative, lucid book, a magnificent achievement." And, *The Economist*, which started the debate by publishing his first articles, announced that, "this is one of the most valuable books on public policy—not merely on environmental policy—to have been written in the past ten years."

Among most environmentalists and scientists, on the other hand, Lomborg has become an anathema. A widely circulated list of "Ten things you should know about the Skeptical Environmentalist" charged that the book is full of pseudo-scholarship, statistical fallacies, distorted quotations, inaccurate or misleading citations, misuse of data, interpretations that contradict well-established scientific work, and many other serious errors. This list accuses Lomborg of having no professional credentials or training—and having done no professional research—in **ecology**, **climate** science, resource economic, **environmental policy**, or other fields covered by his book. In essence, they complain, "Who is this guy, and how dare he say all this terrible stuff?"

Harvard University Professor **E. O. Wilson**, one of the world's most distinguished biologists, deplores what he calls "the Lomborg scam," and says that he and his kind "are the parasite load on scholars who earn success through the slow process of peer review and approval." It often seems that more scorn and hatred is focused on those, like Lomborg, who are viewed as a turncoats and heretics, than for those who are actually out despoiling the environment and squandering resources.

Perhaps the most withering criticism of Lomborg comes from his reporting of statistics and research results. Stephen Schneider, a distinguished climate scientist from Stanford University, for instance, writes in *Scientific American* "most of [Lomborg's] nearly 3,000 citations are to secondary literature and media articles. Moreover, even when cited, the peer-reviewed articles come elliptically from those studies

that support his rosy view that only the low end of the uncertainty ranges [of climate change] will be plausible. IPCC authors, in contrast, were subjected to three rounds of review by hundreds of outside experts. They didn't have the luxury of reporting primarily from the part of the community that agrees with their individual views."

Lomborg also criticizes **extinction** rate estimates as much too large, citing evidence from places like Brazil's Atlantic Forest, where about 90% of the forest has been cleared without large numbers of recorded extinctions. Thomas Lovejoy, chief **biodiversity** adviser to the **World Bank**, responds, "First, this is a region with very few field biologists to record either species or their extinction. Second, there is abundant evidence that if the Atlantic forest remains as reduced and fragmented as it is, will lose a sizable fraction of the species that at the moment are able to hang on."

Part of the problem is that Lomborg is unabashedly anthropocentric. He dismisses the value of biodiversity, for example. As long as there are plants and animals to supply human needs, what does it matter if a few non-essential species go extinct? In Lomborg's opinion, poverty, hunger, and human health problems are much more important problems than **endangered species** or possible climate change. He isn't opposed to reducing greenhouse gas emissions, for instance, but argues that rather than spend billions of dollars per year to try to meet Kyoto standards, we could provide a healthy diet, clean water, and basic medical services to everyone in the world, thereby saving far more lives than we might do by reducing global climate change. Furthermore, Lomborg believes, **solar energy** will probably replace **fossil fuels** within 50 years anyway, making worries about increasing CO_2 concentrations moot.

Lomborg infuriates many environmentalists by being intentionally optimistic, cheerfully predicting that progress in population control, use of **renewable energy**, and unlimited water supplies from desalination technology will spread to the whole world, thus avoiding crises in resource supplies and human impacts on our environment. Others, particularly Lester Brown of the **Worldwatch Institute** and Professor Paul Ehrlich of Stanford University, according to Lomborg, seem to deliberately adopt worst-case scenarios.

Protagonists on both sides of this debate use statistics selectively and engage in deliberate exaggeration to make their points. As Stephen Schneider, one of the most prominent anti-Lomborgians, said in an interview in *Discover* in 1989, "[We] are not just scientists but human beings as well. And like most people we'd like to see the world a better place. To do that we need to get some broad-based support, to capture the public's imagination. That, of course, entails getting loads of media coverage. So we have to offer up scary scenarios, make simplified, dramatic statements, and make little mention of any doubts we might have. Each of us has to decide what the right balance is between being effective and being honest."

As is often the case in complex social issues, there are both truth and error on both sides in this debate. It takes good critical thinking skills to make sense out of the flurry of charges and counter charges. In the end, what you believe depends on your perspective and your values. Future events will show us whether Bjørn Lomborg or his critics are correct in their interpretations and predictions. In the meantime, it's probably healthy to have the vigorous debate engendered by strongly held beliefs and articulate partisans from many different perspectives.

In November 2001, Lomborg was selected Global Leader for Tomorrow by the World Economic Forum, and in February 2002, he was named director of Denmark's national Environmental Assessment Institute. In addition to the use of statistics in environmental issues, his professional interests are simulation of strategies in collective action dilemmas, simulation of party behavior in proportional voting systems, and use of surveys in public administration.

Barry Holstun Lopez (1945 –)

American environmental writer

Barry Lopez has often called his own nonfiction writing natural history, and he is often categorized as a **nature** writer. This partially describes his work, but limiting him to that category is misleading, partly because his work transcends the kinds of subjects implicit in that classification. He could as well, for example, be called a travel writer, though that label also does not completely describe his work. He has in addition published a number of unusual works of fiction, and even has one children's book (on *Crow and Weasel*) to his credit.

Barry Lopez was born in Port Chester, New York, but he spent several early childhood years in rural southern California and, at the age of 10, returned to the East to grow up in New York City. He earned a BA degree from the University of Notre Dame, followed by an MAT from the University of Oregon in 1968. His initial goal was to teach, but in the late 1960s he set out to become a professional writer and since 1970 has earned his living writing (as well as by lecturing and giving readings).

Lopez's nonfiction writing transcends the category of natural history because his real topic, as Rueckert suggests, is the search for human relationships with nature, relationships that are "dignified and honorable." Natural history as a category of literature implies a focus on primeval nature undisturbed by human activity, or at least on nature as it exists in its own right rather than as humans relate to it. He is a practitioner of what some have called "the new naturalism—a search for the human as mirrored in nature." Lopez's focus then is **human ecology**, the interactions of human beings with the world around them, especially the natural world. Even his most "natural" book of natural history, *Of Wolves and Men*, is not just about the natural history of **wolves** but about how that species' existence or "being" in the wild is affected by human perceptions and actions, and it is as well about the image of the wolf in human minds.

His fiction works can be called unusual, partly because they are often presented as brief notes or sketches, and partly because they are frequently blended into and combined with legends, factual observations of nature, and personal meditations. Everything Lopez writes, however, is in the form of a story, whether fiction, natural history, folklore, or travel writing. His story-telling makes all of his writing enjoyable to read, easy to access and ingest, and often memorable.

Lopez as a story teller, occupies the spaces between truth-teller and mystic, between natural scientist and folklorist. He has written of wolves and humans, and then of people with blue skins who could not speak and, apparently, subsisted only on clean air. He writes of the land in reality and the land in our imaginations, frequently in the same text. His writings on natural history provide the reader with great detail about the places in the world he describes, but his fiction can force the shock of recognition of places in the mind. In 1998, Lopez was a National Magazine Award in Fiction finalist for *The Letters of Heaven* and in 1999 he received the Lannan residency fellowship.

Barry Lopez is in part a naturalist, in the best sense of that word. He is also something of an anthropologist. He is a student of folklore and mythology. He travels widely, but he studies his own home place and local **environment** intently. And, of course, he is a writer.

Los Angeles Basin

The second most populous city in the United States, Los Angeles has perhaps the most fascinating **environmental history** of any urban area in the country. The Los Angeles Basin, into which more than 80 communities of Los Angeles County are crowded, is a trough-shaped region bounded on three sides by the Santa Monica, Santa Susana, San Gabriel, San Bernadino, and Santa Ana Mountains. On its fourth side, the county looks out over the Pacific Ocean.

The earliest settlers arrived in the Basin in 1769 when Spaniard Gaspar de Portolá and his expedition set up camp

along what is now known as the Los Angeles River. The site was eventually given the name El Pueblo de la Reyna de Los Angeles (the Town of the Queen of the Angels).

For the first century of its history, Los Angeles grew very slowly. Its population in 1835 was only 1,250. By the end of the century, however, the first signs of a new trend appeared. In response to the promises of sunshine, warm weather, and "easy living," immigrants from the East Coast began to arrive in the Basin. Its population more than quadrupled between 1880 and 1890, from 11,183 to 50,395.

The rush was on, and it has scarcely abated today. The metropolitan population grew from 102,000 in 1900 to 1,238,000 in 1930 to 3,997,000 in 1950 to 9,838,861 in 2000.

The **pollution** facing Los Angeles today results from a complex mix of natural factors and intense **population growth**. The first reports of Los Angeles's famous **photochemical smog** go back to 1542. The "many smokes" described by Juan Cabrillo in that year were not the same as today's **smog**, but they occurred because of geographic and climatic conditions that are responsible for modern environmental problems.

The Los Angeles Basin has one of the highest probabilities of experiencing thermal inversions of any area in the United States. An inversion is an atmospheric condition in which a layer of cold air becomes trapped beneath a layer of warm air. That situation is just the reverse of the most normal atmospheric condition in which a warm layer near the ground is covered by a cooler layer above it. The warm air has a tendency to rise, and the cool air has a tendency to sink. As a result, natural mixing occurs. In contrast, when a thermal inversion occurs, the denser cool air remains near the ground while the less dense air above it tends to stay there.

Smoke and other pollutants released into a thermal inversion are unable to rise upward and tend to be trapped in the cool lower layer. Furthermore, horizontal movements of air, which might clear out pollution in other areas, are blocked by the mountains surrounding LA county. The lingering **haze** of the "many smokes" described by Cabrillo could have been nothing more than the smoke from campfires trapped by inversions that must have existed even in 1542.

As population and industrial growth occurred in Los Angeles during the second half of the twentieth century, the amount of pollutants trapped in thermal inversions also grew. By the 1960s, Los Angeles had become a classic example of how modern cities were being choked by their own wastes.

The geographic location of the Los Angeles Basin contributes another factor to Los Angeles's special environmental problems. Sunlight warms the Basin for most of the year and attracts visitors and new residents. **Solar energy** fuels reactions between components of Los Angeles's polluted air, producing **chemicals** even more toxic than those from which they came. The complex mixture of noxious compounds produced in Los Angeles has been given the name *smog*, reflecting the combination of human (*sm*oke) and natural factors (f*og*) that make it possible. Smog, also called ground level **ozone**, can cause a myriad of health problems including breathing difficulties, coughing, chest pains, and congestion. It may also exacerbate **asthma**, heart disease, and **emphysema**.

As Los Angeles grew in area and population, conditions which guaranteed a continuation of smog increased. The city and surrounding environs eventually grew to cover 400 square miles (1,036 square kilometers), a widespread community held together by freeways and cars. A major oil company bought the city's public transit system, then closed it down, ensuring the wide use of **automobile transportation**. Thus, gases produced by the **combustion** of **gasoline** added to the city's increasing pollution levels.

Los Angeles and the State of California have been battling **air pollution** for over 20 years. California now has some of the strictest **emission standards** of any state in the nation, and LA has begun to develop **mass transit** systems once again. For an area that has long depended on the automobile, however, the transition to public transportation has not been an easy one. But some measurable progress has been made in controlling ground level ozone. In 1976, smog was detectable at levels above the state standard acceptable average of 0.09 ppm a staggering 237 days out of the year. By 2001, the number had dropped to 121 days. Still, much work remains to be done; in 2000, 2001, and 2002 Los Angeles topped the American Lung Association's annual list of most ozone polluted cities and counties.

Another of Los Angeles's population-induced problems is its enormous demand for water. As early as 1900, it was apparent that the Basin's meager **water resources** would be inadequate to meet the needs of the growing urban area. The city turned its sights on the Owens Valley, 200 mi (322 km) to the northeast in the Sierra Nevada. After a lengthy dispute, the city won the right to tap the water resources of this distant valley. A 200-mile water diversion public works project, the Los Angeles Aqueduct, was completed in 1913.

This development did not satisfy the area's growing need for water, however, and in the 1930s, a second canal was built. This canal, the **Colorado River** Aqueduct, carries water from the Colorado River to Los Angeles over a distance of 444 mi (714 km). Even this proved to be inadequate, however, and the search for additional water sources has gone on almost without stop. In fact, one of the great ongoing debates in California is between legislators from

Northern California, where the state's major water resources are located, and their counterparts from Southern California, where the majority of the state's people live. Since the latter contingent is larger in number, it has won many of the battles so far over distribution of the state's water resources.

Of course, Los Angeles has also experienced many of the same problems as urban areas in other parts of the world, regardless of its special geographical character. For example, the Basin was at one time a lush agricultural area, with some of the best **soil** and growing conditions found anywhere. From 1910 to 1950, Los Angeles County was the wealthiest agricultural region in the nation. But as urbanization progressed, more and more farmland was sacrificed for commercial and residential development. During the 1950s, an average of 3,000 acres (1,215 hectares) of farmland per day was taken out of production and converted to residential, commercial, industrial, or transportation use.

One of the mixed blessings faced by residents of the Los Angeles Basin is the existence of large oil reserves in the area. On the one hand, the oil and **natural gas** contained in these reserves is a valuable natural resource. On the other hand, the presence of working oil **wells** in the middle of a modern metropolitan area creates certain problems. One is aesthetic, as busy pumps in the midst of barren or scraggly land contrasts with sleek new glass and steel buildings.

Another petroleum-related difficulty is that of land **subsidence**. As oil and gas are removed from underground, land above it begins to sink. This phenomenon was first observed as early as 1937. Over the next two decades, subsidence had reached 16 ft (5 m) at the center of the Wilmington oil fields. Horizontal shifting of up to 9 ft (2.74 m) was also recorded.

Estimates of subsidence of up to 45 ft (14 m) spurred the county to begin remedial measures in the 1950s. These measures included the construction of levees to prevent seawater from flowing into the subsided area and the repressurizing of oil zones with water injection. These measures have been largely successful, at least to the present time, in halting the subsidence of the oil field.

Los Angeles' annual ritual of pumping and storing water into underground aquifers in anticipation of the long, dry summer season has also been responsible for elevation shifts in the region. Researchers with the United States **Geological Survey** (USGS) observed that the ground surface of a 20 by 40 km area of Los Angeles rises and falls approximately 10–11 centimeters annually in conjunction with the water storage activities.

As if population growth itself were not enough, the Basin poses its own set of natural challenges to the community. For example, the area has a typical Mediterranean **climate** with long hot summers, and short winters with little rain. Summers are also the occasion of Santa Ana winds, severe windstorms in which hot air sweeps down out of the mountains and across the Basin. Urban and forest fires that originate during a Santa Ana wind not uncommonly go out of control causing enormous devastation to both human communities and the natural **environment**.

The Los Angeles Basin also sits within a short distance of one of the most famous fault systems in the world, the San Andreas Fault. Other minor faults spread out around Los Angeles on every side. Earthquakes are common in the Basin, and the most powerful **earthquake** in Southern California history struck Los Angeles in 1857 (8.25 magnitude). Sixty miles (97 kilometers) from the quake's epicenter, the tiny community of Los Angeles lost the military base at Fort Tejon although only two lives were lost in the disaster. Like San Franciscans, residents of the Los Angeles Basin live not wondering if another earthquake will occur, but only when "The Big One" will hit. *See also* Air quality; Atmospheric inversion; Environmental Protection Agency (EPA); Mass transit; Oil drilling

Love Canal

Probably the most infamous of the nation's **hazardous waste** sites, the Love Canal neighborhood of Niagara Falls, New York, was largely evacuated of its residents in 1980 after testing revealed high levels of toxic **chemicals** and genetic damage.

Between 1942 and 1953, the Olin Corporation and the Hooker Chemical Corporation buried over 20,000 tons of deadly chemical waste in the canal, much of which is known to be capable of causing **cancer**, **birth defects**, miscarriages, and other health disorders. In 1953, Hooker deeded the land to the local board of education but did not clearly warn of the deadly nature of the chemicals buried

Weeds grow around boarded up homes in Love Canal, New York in 1980. (Corbis-Bettmann. Reproduced by permission.)

there, even when homes and playgrounds were built in the area.

The seriousness of the situation became apparent in 1976, when years of unusually heavy rains raised the **water table** and flooded basements. As a result, houses began to reek of chemicals, and children and pets experienced chemical burns on their feet. Plants, trees, gardens, and even some pets died.

Soon neighborhood residents began to experience an extraordinarily high number of illnesses, including cancer, miscarriages, and deformities in infants. Alarmed by the situation, and frustrated by inaction on the part of local, state, and federal governments, a 27-year-old housewife named Lois Gibbs began to organize her neighbors. In 1978 they formed the Love Canal Homeowners Association and began a two-year fight to have the government relocate them into another area.

In August 1978 the New York State Health Commissioner recommended that pregnant women and young children be evacuated from the area, and subsequent studies documented the extraordinarily high rate of birth defects, miscarriages, genetic damage and other health affects. In 1979, for example, of 17 pregnant women in the neighborhood, only two gave birth to normal children. Four had miscarriages, two suffered stillbirths, and nine had babies with defects.

Eventually, the state of New York declared the area "a grave and imminent peril" to human health. Several hundred families were moved out of the area, and the others were advised to leave. The school was closed and barbed wire placed around it. In October 1980 President Jimmy Carter declared Love Canal a national disaster area.

In the end, some 60 families decided to remain in their homes, rejecting the government's offer to buy their properties. The cost for the cleanup of the area has been estimated at $250 million. Ironically, twelve years after the neighborhood was abandoned, the state of New York approved plans to allow families to move back to the area, and homes were allowed to be sold.

Love Canal is not the only hazardous waste site in the country that has become a threat to humans--only the best known. Indeed, the United States **Environmental Protection Agency** has estimated that up to 2,000 hazardous waste disposal sites in the United States may pose "significant risks

to human health or the environment," and has called the toxic waste problem "one of the most serious problems the nation has ever faced." *See also* Contaminated soil; Hazardous waste site remediation; Hazardous waste siting; Leaching; Storage and transport of hazardous material; Stringfellow Acid Pits; Toxic substance

Sir James Ephraim Lovelock (1919 –)

English chemist

Sir James Lovelock is the framer of the **Gaia hypothesis** and developer of, among many other devices, the electron capture gas chromatographic detector. The highly selective nature and great sensitivity of this detector made possible not only the identification of **chlorofluorocarbons** in the **atmosphere**, but led to the measurement of many pesticides, thus providing the raw data that underlie Rachel Carson's *Silent Spring*.

Sir James Lovelock was born in Letchworth Garden City, earned his degree in chemistry from Manchester University, and took a Ph.D. in medicine from the London School of Hygiene and Tropical Medicine. His early studies in medical topics included work at Harvard University Medical School and Yale University. He spent three years as a professor of chemistry at Baylor University College of Medicine in Houston, Texas. It was from that position that his work with the Jet Propulsion Laboratory for NASA began.

The Gaia hypothesis, Sir James Lovelock's most significant contribution to date, grew out of the work of Sir James Lovelock and his colleagues at the lab. While attempting to design experiments for life detection on Mars, Sir James Lovelock, Dian Hitchcock, and later Lynn Margulis, posed the question, "If I were a Martian, how would I go about detecting life on Earth?" Looking in this way, the team soon realized that our atmosphere is a clear sign of life and it is totally impossible as a product of strictly chemical equilibria. One consequence of viewing life on this or another world as a single homeostatic organism is that energy will be found concentrated in certain locations rather than spread evenly, frequently, or even predominantly, as chemical energy. Thus, against all **probability**, the earth has an atmosphere containing about 21% free oxygen and has had about this much for millions of years. Sir James Lovelock bestowed on this superorganism comprising the whole of the **biosphere** the name "Gaia," one spelling of the name of the Greek earth-goddess, at the suggestion of a neighbor, William Golding, author of *Lord of the Flies*.

Sir James E. Lovelock at his home in Cornwall with thedevice he invented to measure chlorofluorocarbons in the atmosphere. (Photograph by Anthony Howarth. Photo Researchers Inc. Reproduced by permission.)

Sir James Lovelock's hypothesis was initially attacked as requiring the whole of life on earth to have purpose, and hence in some sense, common intelligence. Sir James Lovelock then developed a computer model called "Daisyworld" in which the presence of black and white daisies controlled the global temperature of the planet to a nearly constant value despite a major increase in the heat output of its sun. The concept that the biosphere keeps the **environment** constant has been attacked as sanctioning

environmental degradation, and accusers took a cynical view of Sir James Lovelock's service to the British **petrochemical** industry. However, the hypothesis has served the environmental community well in suggesting many ideas for further studies, virtually all of which have given results predicted by the hypothesis.

Since 1964, Sir James Lovelock has operated a private consulting practice, first out of his home in Bowerchalke, near Salisbury, England, and later from a home near Launceston, Cornwall. He has authored over 200 scientific papers, covering research that ranged from techniques for freezing and successfully reviving hamsters to global systems science, which he has proposed to call geophysiology. Sir James Lovelock has been honored by his peers worldwide with numerous awards and honorary degrees, including Fellow of the Royal Society. He was also named a Commander of the British Empire by Queen Elizabeth in 1990.

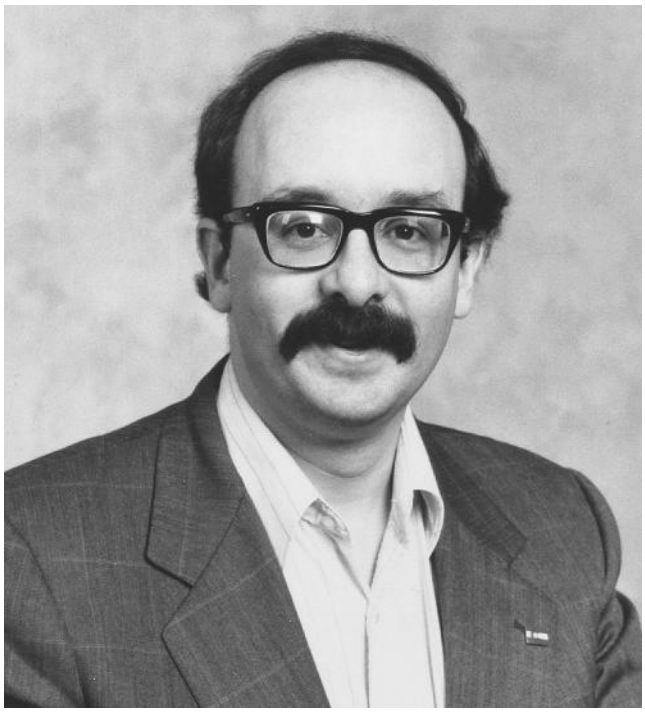
Amory Bloch Lovins (1947 –)

American physicist and energy conservationist

Amory Lovins is a physicist specializing in environmentally safe and sustainable energy sources. Born in 1947 in Washington, D.C., Lovins attended Harvard and Oxford universities. He has had a distinguished career as an educator and scientist. After resigning his academic post at Oxford in 1971, Lovins became the British representative of **Friends of the Earth**. He has been Regents' Lecturer at the University of California at Berkeley and has served as a consultant to the United Nations and other international and environmental organizations. Lovins is a leading critic of hard energy paths and an outspoken proponent of soft alternatives.

According to Lovins, an energy path is "hard" if the route from source to use is complex and circuitous requires extensive, expensive, and highly complex technological means and centralized power to produce, transmit, and store the energy produces toxic wastes or other unwanted side effects has hazardous social uses or implications and tends over time to harden even more, as other options are foreclosed or precluded as the populace becomes ever more dependent on energy from a particular source. A hard energy path can be seen in the case of fossil fuel energy. Once readily abundant and cheap, **petroleum** fueled the internal **combustion** engines and other machines on which humans have come to depend, but as that energy source becomes scarcer, oil companies must go farther afield to find it, potentially causing more environmental damage. As oil supplies run low and become more expensive, the temptation is to sustain the level of energy use by turning to another, and even harder, energy path—nuclear energy.



With its complex technology, its hazards, its long-lived and highly toxic wastes, its myriad military uses, and the possibility of its falling into the hands of dictators or terrorists, **nuclear power** is perhaps the hardest energy path. No less important are the social and political implications of this hard path: radioactive wastes will have to be stored somewhere nuclear **power plants** and **plutonium** transport routes must be guarded we must make trade-offs between the ease, convenience, and affluence of people presently living and the health and well-being of **future generations** and so on. A hard energy path is also one that, once taken, forecloses other options because, among other considerations, the initial investment and costs of entry are so high as to render the decision, once made, nearly irreversible. The longer term economic and social costs of taking the hard path, Lovins argues, are astronomically high and incalculable.

Soft energy paths, by contrast, are shorter, more direct, less complex, cheaper (at least over the long run), are inexhaustible and renewable, have few if any unwanted side-effects, have minimal military uses, and are compatible with decentralized local forms of community control and decision-making. The old windmill on the family farm offers an early example of such a soft energy source newer versions of the windmill, adapted to the generation of electricity, supply a more modern example. Other soft technologies include **solar energy**, **biomass** furnaces burning peat, dung or wood chips, and **methane** from the rotting of vegetable matter, manure, and other cheap, plentiful, and readily available organic material.

Much of Lovins's work has dealt with the technical and economic aspects, as well as the very different social impacts and implications, of these two competing energy paths. A resource consultant agency, The **Rocky Mountain Institute**, was founded by Lovins and his wife, Hunter in 1982. In 1989, Lovins and his wife won the Onassis Foundation's first Delphi Prize for their "essential contribution towards finding alternative solutions to energy problems."

Lowest Achievable Emission Rate

Governments have explored a number of mechanisms for reducing the amount of pollutants released to the air by factories, **power plants**, and other stationary sources. One mechanism is to require that a new or modified installation releases no more pollutants than determined by some law or regulation determining the lowest level of pollutants that can be maintained by existing technological means. These limits are known as the Lowest Achievable Emission Rate (LAER). The **Clean Air Act** of 1970 required, for example, that any new source in an area where minimum **air pollution** standards were not being met had to conform to the LAER standard. *See also* Air quality; Best Available Control Technology (BAT); Emission standards

Low-head hydropower

The term hydropower often suggests giant **dams** capable of transmitting tens of thousands of cubic feet of water per minute. Such dams are responsible for only about six percent of all the electricity produced in the United States today.

Hydropower facilities do not have to be massive buildings. At one time in the United States--and still, in many places around the world--electrical power is generated at low-head facilities, dams where the vertical drop through which water passes is a relatively short distance and/or where water flow is relatively modest. Indeed, the first commercial hydroelectric facility in the world consisted of a waterwheel on the Fox River in Appleton, Wisconsin. The facility, opened in 1882, generated enough electricity to operate lighting systems at two paper mills and one private residence.

Electrical demand grew rapidly in the United States during the early twentieth century, and hydropower supplied much of that demand. By the 1930s, nearly 40 percent of the electricity used in this country was produced by hydroelectric facilities. In some Northeastern states, hydropower accounted for 55-85 percent of the electricity produced.

A number of social, economic, political, and technical changes soon began to alter that pattern. Perhaps most important was the vastly increased efficiency of **power plants** operated by **fossil fuels**. The fraction of electrical power from such plants rose to more than 80 percent by the 1970s.

In addition, the United States began to move from a decentralized energy system in which many local energy companies met the needs of local communities, to large, centralized utilities that served many counties or states. In the 1920s, more than 6,500 electric power companies existed in the nation. As the government recognized power companies as monopolies, that number began to drop rapidly. Companies that owned a handful of low-head dams on one or more rivers could no longer compete with their giant cousins that operated huge plants powered by oil, **natural gas**, or **coal**.

As a result, hundreds of small hydroelectric plants around the nation were closed down. According to one study, over 770 low-head hydroelectric plants were abandoned between 1940 and 1980. In some states, the loss of low-head generating capacity was especially striking. Between 1950 and 1973, Consumers Power Company, one of Michigan's two **electric utilities**, sold off 44 hydroelectric plants.

Some experts believe that low-head hydropower should receive more attention today. Social and technical factors still prevent low-head power from seriously compet-

ing with other forms of energy on a national scale. But it may meet the needs of local communities in special circumstances. For example, a project has been undertaken to rehabilitate four low-head dams on the Boardman River in northwestern Michigan. The new facility is expected to increase the electrical energy available to nearby Traverse City and adjoining areas by about 20 percent.

Low-head hydropower appears to have a more promising future in less-developed parts of the world. For example, China has more than 76,000 low-head dams that generate a total of 9,500 megawatts of power. An estimated 50 percent of rural townships depend on such plants to meet their electrical needs. Low-head hydropower is also of increasing importance in nations with fossil-fueled plants and growing electricity needs. Among the fastest growing of these are Peru, India, the Philippines, Costa Rica, Thailand, and Guatemala. *See also* Alternative energy sources; Electric utilities; Wave power

Low-level radioactive waste

Low-level **radioactive waste** consists of materials used in a variety of medical, industrial, commercial, and research applications. They tend to release a low level of radiation that dissipates in a relatively short period of time. Although care must be taken in handling such materials, they pose little health or environmental risk. Among the most common low level radioactive materials are rags, papers, protective clothing, and **filters**. Such materials are often stored temporarily in sealed containers at their use site. They are then disposed of by burial at one of three federal sites: Barnwell, South Carolina, Beatty, Nevada, or Hanford, Washington. *See also* Hanford Nuclear Reservation; High-level radioactive waste; Radioactive waste; Radioactivity

Sir Charles Lyell (1797 – 1875)

Scottish geologist

Lyell was born in Kinnordy, Scotland, the son of well-to-do parents. When Lyell was less than a year old, his father moved his family to the south of England where he leased a house near the New Forest in Hampshire. Lyell spent his boyhood there, surrounded by his father's collection of rare plants. At the age of seven, Lyell became ill with pleurisy and while recovering began to collect and study insects. As a young man he entered Oxford to study law, but he also became interested in mineralogy after attending lectures by the noted geologist William Buckland. Buckland advocated the theories of Abraham Gottlob Werner, a neptunist who postulated that a vast ocean once covered the earth and that the various rocks resulted from chemical and mechanical deposition underwater, over a long period of time. This outlook was more in keeping with the Biblical story of Genesis than that of the vulcanists or plutonists who suscribed to the idea that volcanism, along with **erosion** and deposition, were the major forces sculpting the Earth. While on holidays with his family, Lyell made the first of many observations in hopes of confirming the views of Buckland and Werner. However, he continued to study law and was eventually called to the bar in 1822. Lyell practiced law until 1827 while still devoting time to geology.

Lyell traveled to France and Italy where he collected extensive data which caused him to reject the neptunist philosophy. He instead drew the conclusion that volcanic activity and erosion by wind and weather were primarily responsible for the different strata rather than the deposition of sediments from a "world ocean." He also rejected the catastrophism of Georges Cuvier, who believed that global catastrophes, such as the biblical Great Flood, periodically destroyed life on Earth, thus accounting for the different fossils found in each rock layer. Lyell believed change was a gradual process that occurred over a long period of time at a constant rate. This theory, known as uniformitarianism, had been postulated 50 years earlier by Scottish geologist James Hutton. It was Lyell, though, who popularized uniformitarianism in his work *The Principles of Geology*, which is now considered a classic text in this field. By 1850 his views and those of Hutton had become the standard among geologists. However, unlike many of his colleagues, Lyell adhered so strongly to uniformitarianism that he rejected the possibility of even limited catastrophe. Today most scientists accept that catastrophes such as meteor impacts played an important, albeit supplemental, role in the earth's **evolution**.

In addition to his championing of uniformitarianism, Lyell named several divisions of geologic time such as the Eocene, Miocene, and Pliocene Epochs. He also estimated the age of some of the oldest fossil-bearing rocks known at

that time, assigning them the then startling figure of 240 million years. Even though Lyell came closer than his contemporaries to guessing the correct age, it is still less than half the currently accepted figure used by geologists today. While working on *The Principles of Geology*, Lyell formed a close friendship with Charles Darwin who had outlined his evolutionary theory in *The Origin of Species*. Both scientists quickly accepted the work of the other (Lyell was one of two scientists who presented Darwin's work to the influential Linnaean Society). Lyell even extended evolutionary theory to include humans at a time when Darwin was unwilling to do so. In his *The Antiquity of Man* (1863), Lyell argued that humans were much more ancient than creationists (those who interpreted Book of Genesis literally) and catastrophists believed, basing his ideas on archaeological artifacts such as ancient ax heads. Lyell was knighted for his work in 1848 and created a baronet in 1864. He also served as president of the Geological Society and set up the Lyell Medal and the Lyell Fund. He died in 1875 while working on the twelfth edition of his *Principles of Geology*.

M

Robert Helmer MacArthur (1930 – 1972)

Canadian biologist and ecologist

Few scientists have combined the skills of mathematics and biology to open new fields of knowledge the way Robert H. MacArthur did in his pioneering work in evolutionary **ecology**. Guided by a wide-ranging curiosity for all things natural, MacArthur had a special interest in birds and much of his work dealt primarily with bird populations. His conclusions, however, were not specific to ornithology but transformed both **population biology** and **biogeography** in general.

Robert Helmer MacArthur was born in Toronto, Ontario, Canada, on April 7, 1930, the youngest son of John Wood and Olive (Turner) MacArthur. While Robert spent his first seventeen years attending public schools in Toronto, his father shuttled between the University of Toronto and Marlboro College in Marlboro, Vermont, as a professor of genetics. Robert MacArthur graduated from high school in 1947 and immediately immigrated to the United States to attend Marlboro College. He received his undergraduate degree from Marlboro in 1951 and a master's degree in mathematics from Brown University in 1953. Upon receiving his doctorate in 1957 from Yale University under the direction of G. Evelyn Hutchinson, MacArthur headed for England to spend the following year studying ornithology with David Lack at Oxford University. When he returned to the United States in 1958, he was appointed Assistant Professor of Biology at the University of Pennsylvania.

As a doctoral student at Yale, MacArthur had already proposed an ecological theory that encompassed both his background as a mathematician and his growing knowledge as a naturalist. While at Pennsylvania, MacArthur developed a new approach to the frequency distribution of **species**. One of the problems confronting ecologists is measuring the numbers of a specific species within a geographic area—one cannot just assume that three crows in a 10-acre corn field means that in a 1000-acre field there will be 300 crows. Much depends on the number of species occupying a **habitat**, species **competition** within the habitat, food supply, and other factors. MacArthur developed several ideas relating to the measurement of species within a known habitat, showing how large masses of empirical data relating to numbers of species could be processed in a single model by employing the principles of information theory. By taking the sum of the product of the frequencies of occurrences of a species and the logarithms of the frequencies, complex data could be addressed more easily.

The most well-known theory of frequency distribution MacArthur proposed in the late 1950s is the so-called broken stick model. This model had been suggested by MacArthur as one of three competing models of frequency distribution. He proposed that competing species divide up available habitat in a random fashion and without overlap, like the segments of a broken stick. In the 1960s, MacArthur noted that the theory was obsolete. The procedure of using competing explanations and theories simultaneously and comparing results, rather than relying on a single hypothesis, was also characteristic of MacArthur's later work.

In 1958, MacArthur initiated a detailed study of warblers in which he analyzed their **niche** division, or the way in which the different species will to be best suited for a narrow ecological role in their common habitat. His work in this field earned him the Mercer Award of the **Ecological Society of America**. In the 1960s, he studied the so-called "species-packing problem." Different kinds of habitat support widely different numbers of species. A **tropical rain forest** habitat, for instance, supports a great many species, while arctic **tundra** supports relatively few. MacArthur proposed that the number of species crowding a given habitat correlates to niche breadth. The book *The Theory of Island Biogeography*, written with **biodiversity** expert Edward O. Wilson and published in 1967, applied these and other ideas to isolated habitats such as islands. The authors explained the species-packing problem in an evolutionary light, as an equilibrium between the rates at which new species arrive or develop and the **extinction** rates of species already present.

These rates vary with the size of the habitat and its distance from other habitats.

In 1965 MacArthur left the University of Pennsylvania to accept a position at Princeton University. Three years later, he was named **Henry Fairfield Osborn** Professor of Biology, a chair he held until his death. In 1971, MacArthur discovered that he suffered from a fatal disease and had only a few years to live. He decided to concentrate his efforts on encapsulating his many ideas in a single work. The result, *Geographic Ecology: Patterns in the Distribution of Species*, was published shortly before his death the following year. Besides a summation of work already done, *Geographic Ecology* was a prospectus of work still to be carried out in the field.

MacArthur was a Fellow of the American Academy of Arts and Science. He was also an Associate of the Smithsonian Tropical Research Institute, and a member of both the Ecological Society and the National Academy of Science. He married Elizabeth Bayles Whittemore in 1952; they had four children: Duncan, Alan, Donald, and Elizabeth. Robert MacArthur died of renal **cancer** in Princeton, New Jersey, on November 1, 1972, at the age of 42.

Mad cow disease

Mad cow disease, a relatively newly discovered malady, was first identified in Britain in 1986, when farmers noticed that their cows' behavior had changed. The cows began to shake and fall, became unable to walk or even stand, and eventually died or had to be killed. It was later determined that a variation of this fatal neurological disease, formally known as Bovine Spongiform Encephalopathy (BSE), could be passed on to humans.

It is still not known to what extent the population of Britain and perhaps other countries is at risk from consumption of contaminated meat and animal by-products. The significance of the BSE problem lies in its as yet unquantifiable potential to not only damage Britain's $7.5 billion beef industry, but also to endanger millions of people with the threat of a fatal brain disease.

A factor that stood out in the autopsies of infected animals was the presence of holes and lesions in the brains, which were described as resembling a sponge or Swiss cheese. This was the first clue that BSE was a subtype of untreatable, fatal brain diseases called transmissible spongiform encephalopathies (TSEs). These include a very rare human malady known as Creutzfeldt-Jakob Disease (CJD), which normally strikes just one person in a million, usually elderly or middle-aged. In contrast to previous cases of CJD, the new bovine-related CJD in humans is reported to affect younger people, and manifests with unusual psychiatric and sensory abnormalities that differentiate it from the endemic CJD. The BSE-related CJD has a delayed onset that includes shaky limb movements, sudden muscle spasms, and dementia.

As the epidemic of BSE progressed, the number of British cows diagnosed began doubling almost yearly, growing from some 7,000 cases in 1989, to 14,000 in 1990, to over 25,000 in 1991. The incidence of CJD in Britain was simultaneously increasing, almost doubling between 1990 and 1994 and reaching 55 cases by 1994. In response to the problem and growing public concern, the government's main strategy was to issue reassurances. However, it did undertake two significant measures to try to safeguard public health. In July 1988, it ostensibly banned meat and bone meal from cow feed, but failed to strictly enforce the action. In November 1989, a law that intended to remove those bovine body parts considered to be the most highly infective (brain, spinal cord, spleen, tonsils, intestines, and thymus) from the public food supply was passed. A 1995 government report revealed that half of the time, the law was not being adhered to by slaughterhouses. Thus, livestock—and the public—continued to be potentially exposed to BSE.

As the disease continued to spread, so did public fears that it might be transmissible to humans, and could represent a serious threat to human health. But the British government, particularly the Ministry of Agriculture, Fisheries, and Food (MAFF), anxious to protect the multibillion dollar cattle industry, insisted that there was no danger to humans. However, on March 20, 1996, in an embarrassing reversal, the government officially admitted that there could be a link between BSE and the unusual incidence of CJD among young people. At the time, 15 people had been newly diagnosed with CJD. Shocking the nation and making headlines around the world, the Minister of Health Stephen Dorrell announced to the House of Commons that consumption of contaminated beef was "the most likely explanation" for the outbreak of a new variant CJD in 10 people under the age of 42, including several teenagers. Four dairy farmers, including some with infected herds, had also contracted CJD, as had a Frenchman who died in January 1996.

British authorities estimated that some 163,000 British cows had contracted BSE. But other researchers, using the same database, put the figure at over 900,000, with 729,000 of them having been consumed by humans. In addition, an unknown number had been exported to Europe, traditionally a large market for British cattle and beef. Many non-meat products may also have been contaminated. Gelatin, made from ligaments, bones, skin, and hooves, is found in ice cream, lipstick, candy, and mayonnaise; keratin, made from hooves, horns, nails, and hair, is contained in shampoo; fat and tallow are used in candles, cosmetics, deodorants, soap, margarine, detergent, lubricants, and pesticides; and protein meal is made into medical and pharmaceutical products, **fertilizer**, and **food additives**. Bone meal from dead cows is used as fertilizer on roses and other plants, and is handled and often inhaled by gardeners.

In reaction to the government announcement, sales of beef dropped by 70%, cattle markets were deserted, and even hamburger chains stopped serving British beef. Prime Minister Major called the temporary reaction "hysteria" and blamed the press and opposition politicians for fanning it.

On March 25, 1996, the **European Union** banned the import of British beef, which had since 1990 been excluded from the United States and 14 other countries. Shortly afterwards, in an attempt to have the European ban lifted, Britain announced that it would slaughter all of its 1.2 million cows over the age of 30 months (an age before which cows do not show symptoms of BSE), and began the arduous task of killing and incinerating 22,000 cows a week. The government later agreed to slaughter an additional l00,000 cows considered most at risk from BSE.

A prime suspect in causing BSE is a by-product derived from the rendering process, in which the unusable parts of slaughtered animals are boiled down or "cooked" at high temperatures to make animal feed and other products. One such product, called meat and bone meal (MBM), is made from the ground-up, cooked remains of slaughtered livestock—cows, sheep, chicken, and hogs—and made into nuggets of animal feed. Some of the cows and sheep used in this process were infected with fatal brain disease. (Although MBM was ostensibly banned as cattle feed in 1988, spinal cords continued to be used.)

It is theorized that sheep could have played a major role in initially infecting cows with BSE. For over 200 years, British sheep have been contracting scrapie, another TSE that results in progressive degeneration of the brain. Scrapie causes the sheep to tremble and itch, and to "scrape" or rub up against fences, walls, and trees to relieve the sensation. The disease, first diagnosed in British sheep in 1732, may have recently jumped the **species** barrier when cows ate animal feed that contained brain and spinal cord tissue from diseased sheep. In 1999 the World Health Organization (WHO) implored high-risk countries to assess outbreaks of BSE-like manifestations in sheep and goat stocks. In August 2002, sheep farms in the United Kingdom demonstrated to the WHO that no increase in illnesses potentially linked to BSE occurred in non-cattle livestock. However, that same year, the European Union Scientific Steering Committee (SSC) on the risk of BSE identified the United Kingdom and Portugal as hotspots for BSE infection of domestic cattle relative to other European nations.

Scrapie and perhaps these other spongiform brain diseases are believed to be caused not by a **virus** (as originally thought) but rather by a form of infectious protein-like particles called prions, which are extremely tenacious, surviving long periods of high intensity cooking and heating. They are, in effect, a new form of contagion. The first real insights into the origins of these diseases were gathered in the 1950s by Dr. D. Carleton Gajdusek, who was awarded the 1976 Nobel Prize in Medicine for his work. His research on the fatal degenerative disease "kuru" among the cannibals of Papua, New Guinea, which resulted in the now-familiar brain lesions and cavities, revealed that the malady was caused by consuming or handling the brains of relatives who had just died.

In the United States, Department of Agriculture officials say that the risk of BSE and other related diseases is believed to be small, but cannot be ruled out. No BSE has been detected in the United States, and no cattle or processed beef is known to have been imported from Britain since 1989. However, several hundred mink in Idaho and Wisconsin have died from an ailment similar to BSE, and many of them ate meat from diseased "downer" cows, those that fall and cannot get up. Some experts believe that BSE can occur spontaneously, without apparent exposure to the disease, in one or two cows out of a million every year. This would amount to an estimated 150–250 cases annually among the United States cow population of some 150 million. Moreover, American feed processors render the carcasses of some 100,000 downer cows every year, thus utilizing for animal feed cows that are possibly seriously and neurologically diseased.

In June 1997, the **Food and Drug Administration** (FDA) announced a partial ban on using in cattle feed remains from dead sheep, cattle, and other animals that chew their cud. But the ruling exempts from the ban some animal protein, as well as feed for poultry, pigs, and pets. In March of that year, a coalition of consumer groups, veterinarians, and federal meat inspectors had urged the FDA to include pork in the animal feed ban, citing evidence that pigs can develop a form of TSE, and that some may already have done so. The coalition had recommended that the United States adopt a ban similar to Britain's, where protein from

French farmers protest against an allowance they must pay to bring dead animals to the knackery—a service that was free of charge prior to mad cow disease.

all mammals is excluded from animal feed, and some criticized the FDA's action as "totally inadequate in protecting consumers and public health."

The United States Centers for Disease Control (CDC) has reclassified CJD that is associated with the interspecies transmission of BSE disease-causing factor. The current categorization of CJD is termed new variant CJD (nvCJD) to distinguish it from the extremely rare form of CJD that is not associated with BSE contagion. According to the CDC, there have been 79 nvCJD deaths reported worldwide. By April 2002, the global incidence of nvCJD increased to 125 documented reports. Of these, most (117) were from the United Kingdom. Other countries reporting nvCJD included France, Ireland, and Italy. The CDC stresses that nvCJD should not be confused with the endemic form of CJD. In the United States, CJD seldom occurs in adults under 30 years old, having a median age of death of 68 years. In contrast, nvCJD, associated with BSE, tends to affect a much younger segment of society. In the United Kingdom, the median age of death from nvCJD is 28 years. As of April 2002, no cases of nvCJD have been reported in the United States, and all known worldwide cases of nvCJD have been associated with countries where BSE is known to exist. The first possible infection of a U.S. resident was documented and reported by the CDC in 2002. A 22-year-old citizen of the United Kingdom living in Florida was preliminarily diagnosed with nvCJD during a visit abroad. Unfortunately, the only way to verify a diagnosis with nvCJD is via brain biopsy or autopsy. If confirmed, the CDC and Florida Department of Health claim that this case would be the first reported in the United States.

The outlook for BSE is uncertain. Since tens of millions of people in Britain may have been exposed to the infectious agent that causes BSE, plus an unknown number in other countries, some observers fear that a latent epidemic of serious proportions could be in the offing. (There is also concern that some of the four million Americans alone now diagnosed with Alzheimer's disease may actually be suffering from CJD.) There are others who feel that a general removal of most infected cows and animal brain tissue from the food supply has prevented a human health disaster. But since the incubation period for CJD is thought to be 7–40 years, it will be some time before it is known how many people are already infected and the extent of the problem becomes apparent.

Madagascar

Described as a crown jewel among earth's ecosystems, this 1,000-mi long (1,610-km) island-continent is a microcosm of **Third World** ecological problems. It abounds with unique **species** which are being threatened by the exploding human population. Many scientists consider Madagascar the world's foremost **conservation** priority. Since 1984 united efforts have sought to slow the island's deterioration, hopefully providing a model for treating other problem areas.

Madagascar is the world's fourth largest island, with a **rain forest climate** in the east, **deciduous forest** in the west, and thorn scrub in the south. Its Malagasy people are descended from African and Indonesian seafarers who arrived about 1,500 years ago. Most farm the land using ecologically devastating **slash and burn agriculture** which has turned Madagascar into the most severely eroded land on earth. It has been described as an island with the shape, color, and fertility of a brick; second growth forest does not do well.

Having been separated from Africa for 160 million years, this unique land was sufficiently isolated during the last 40 million years to become a laboratory of **evolution**. There are 160,000 unique species, mostly in the rapidly disappearing eastern rain forests. These include 65 percent of its plants, half of its birds, and all of its reptiles and mammals. Sixty percent of the earth's chameleons live here. Lemurs, displaced elsewhere by monkeys, have evolved into 26 species. Whereas Africa has only one species of baobab tree, Madagascar has six, and one is termite resistant. The thorn scrub abounds with potentially useful poisons evolved for plant defense. One species of periwinkle provides a substance effective in the treatment of childhood (lymphocytic) **leukemia**.

Humans have been responsible for the loss of 93 percent of tropical forest and two-thirds of rain forest. Four-fifths of the land is now barren as the result of **habitat** destruction set in motion by the exploding human population (3.2 percent growth per year). Although **nature** reserves date from 1927, few Malagasy have ever experienced their island's biological wonders; urbanites disdain the bush, and peasants are driven by hunger. If they can see Madagascar's rich ecosystems first hand, it may engender respect which, in turn, may encourage understanding and protection.

The people are awakening to their loss and the impact this may have on all Madagascar's inhabitants. Pride in their island's unique **biodiversity** is growing. The **World Bank** has provided $90 million to develop and implement a 15-year Environmental Action Plan. One private preserve in the south is doing well and many other possibilities exist for the development of **ecotourism**. If **population growth** can be controlled, and high yield farming replaces **slash** and burn agriculture, there is yet hope for preserving the diversity and uniqueness of Madagascar. *See also* Deforestation; Erosion; Tropical rain forest

Magnetic separation

An on-going problem of environmental significance is **solid waste** disposal. As the land needed to simply throw out solid wastes becomes less available, **recycling** becomes a greater priority in **waste management** programs. One step in recycling is the magnetic separation of ferrous (iron-containing) materials. In a typical recycling process, wastes are first shredded into small pieces and then separated into organic and inorganic fractions. The inorganic fraction is then passed through a magnetic separator where ferrous materials are extracted. These materials can then be purified and reused as scrap iron. *See also* Iron minerals; Resource recovery

Malaria

Malaria is a disease that affects hundreds of millions of people worldwide. In the developing world malaria contributes to a high infant **mortality** rate and a heavy loss of work time. Malaria is caused by the single-celled protozoan parasite, *Plasmodium*. The disease follows two main courses: tertian (three day) malaria and quartan (four day) malaria. *Plasmodium vivax* causes benign tertian malaria with a low mortality (5%), while *Plasmodium falciparum* causes malignant tertian malaria with a high mortality (25%) due to interference with the blood supply to the brain (cerebral malaria). Quartan malaria is rarely fatal.

Plasmodium is transmitted from one human host to another by female mosquitoes of the genus *Anopheles*. Thou-

sands of **parasites** in the salivary glands of the mosquito are injected into the human host when the mosquito takes blood. The parasites (in the sporozoite stage) are carried to the host's liver where they undergo massive multiplication into the next stage (cryptozoites). The parasites are then released into the blood stream, where they invade red blood cells and undergo additional division. This division ruptures the red blood cells and releases the next stage (the merozoites), which invade and destroy other red blood cells. This red blood cell destruction phase is intense but short-lived. The merozoites finally develop into the next stage (gametocytes) which are ingested by the biting mosquito.

The pattern of chills and fever characteristic of malaria is caused by the massive destruction of the red blood cells by the merozoites and the accompanying release of parasitic waste products. The attacks subside as the immune response of the human host slows the further development of the parasites in the blood. People who are repeatedly infected gradually develop a limited immunity. Relapses of malaria long after the original infection can occur from parasites that have remained in the liver, since treatment with drugs kills only the parasites in the blood cells and not in the liver. Malaria can be prevented or cured by a wide variety of drugs (quinine, chloroquine, paludrine, proguanil, or pyrimethamine). However, resistant strains of the common **species** of *Plasmodium* mean that some prophylactic drugs (chloroquine and pyrimethamine) are no longer totally effective.

Malaria is controlled either by preventing contact between humans and mosquitoes or by eliminating the mosquito vector. Outdoors, individuals may protect themselves from mosquito bites by wearing protective clothing, applying mosquito repellents to the skin, or by burning mosquito coils that produce **smoke** containing insecticidal pyrethrins. Inside houses, mosquito-proof screens and nets keep the vectors out, while insecticides (DDT) applied inside the house kill those that enter. The aquatic stages of the mosquito can be destroyed by eliminating temporary breeding pools, by spraying ponds with synthetic insecticides, or by applying a layer of oil to the surface waters. Biological control includes introducing fish (*Gambusia*) that feed on mosquito larvae into small ponds. Organized campaigns to eradicate malaria are usually successful, but the disease is sure to return unless the measures are vigilantly maintained. *See also* Epidemiology; Pesticide

Male contraceptives

Current research into male contraceptives will potentially increase the equitability of **family planning** between males and females. This shift will also have the potential to address issues of **population growth** and its related detrimental effects on the **environment**.

While prophylactic condoms provide good barrier protection from unwanted pregnancies, they are not as effective as oral contraceptives for women. Likewise, vasectomies are very effective, but few men are willing to undergo the surgery. There are three general categories of male contraceptives that are being explored. The first category functionally mimics a vasectomy by physically blocking the vas deferens, the channel that carries sperm from the seminiferous tubules to the ejaculatory duct. The second uses heat to induce temporary sterility. The third involves medications to halt sperm production. In essence, this third category concerns the development of "The Pill" for men.

Despite its near 100% effectiveness, there are two major disadvantages to vasectomy that make it unattractive to many men as an option for contraception. The first is the psychological component relating to surgery. Although vasectomies are relatively non-invasive, when compared to taking a pill the procedure seems drastic. Second, although vasectomies are reversible, the rate of return to normal fertility is only about 40%. Therefore, newer "vas occlusive" methods offer alternatives to vasectomy with completely reversible effects. Vas occlusive devices block the flow of or render dysfunctional the sperm in the vas deferens. The most recent form of vas occlusive male contraception, called Reversible Inhibition of Sperm Under Guidance (RISUG), involves the use of a **styrene** that is combined with the chemical DMSO (dimethyl sulfoxide). The complex is injected into the vas deferens. The complex then partially occludes passage of sperm and also causes disruption of sperm cell membranes. As sperm cells contact the RISUG complex, they rupture. It is believed that a single injection of RISUG may provide contraception for up to 10 years. Large safety and efficacy trials examining RISUG are being conducted in India.

Two additional vas occlusive methods of male contraception involve the injection of polymers into the vas deferens. Both methods involve injection of a liquid form of polymer, microcellular polyurethane (MPU) or medical-grade silicon **rubber** (MSR), into the vas deferens where it

hardens within 20 minutes. The resulting plug provides a barrier to sperm. The technique was developed in China, and since 1983 some 300,000 men have reportedly undergone this method of contraception. Reversal of MPU and MSR plugs requires surgical removal of the polymers. Another method involving silicon plugs (called the Shug for short) offers an alternative to injectable plugs. This double-plug design offers a back-up plug should sperm make their way past the first.

Human sperm is optimally produced at a temperature that is a few degrees below body temperature. Infertility is induced if the temperature of the testes is elevated. For this reason, men trying to conceive are often encouraged to avoid wearing snugly-fitting undergarments. The thermal suspensory method of male contraception utilizes specially designed suspensory briefs to use natural body heat or externally applied heat to suppress spermatogenesis. Such briefs hold the testes close to the body during the day, ideally near the inguinal canal where local body heat is greatest. Sometimes this method is also called artificial cryptorchidism since is simulates the infertility seen in men with undescended testicles. When worn all day, suspensory briefs lead to a gradual decline in sperm production. The safety of briefs that contain heating elements to warm the testes is being evaluated. Externally applied heat in such briefs would provide results in a fraction of the time required using body heat. Other forms of thermal suppression of sperm production utilize simple hot water heated to about 116°F(46.7°C). Immersion of the testicles in the warm water for 45 minutes daily for three weeks is said to result in six months of sterility followed by a return to normal fertility. A newer, but essentially identical, method of thermal male contraception uses ultrasound. This simple, painless, and convenient method using ultrasonic waves to heat water results in six-month, reversible sterility within only 10 minutes.

Drug therapy is also being evaluated as a potential form of male contraception. Many drugs have been investigated in male contraception. An intriguing possibility is the observation that a particular class of blood pressure medications, called calcium channel blockers, induces reversible sterility in many men. One such drug, nifedipine, is thought to induce sterility by blocking calcium channels of sperm cell membranes. This reportedly results in cholesterol deposition and membrane instability of the sperm, rendering them incapable of fertilization. Herbal preparations have also been used as male contraceptives. Gossypol, a constituent of cottonseed oil, was found to be an effective and reliable male contraceptive in very large-scale experiments conducted in China. Unfortunately, an unacceptable number of men experienced persistent sterility when gossypol therapy was discontinued. Additionally, up to 10% of men treated with gossypol experienced kidney problems in the studies conducted in China. Because of the potential toxicity of gossypol, the World Health Organization concluded that research on this form of male contraception should be abandoned. Most recently, a form of sugar that sperm interact with in the fertilization process has been isolated from the outer coating of human eggs. An **enzyme** in sperm, called N-acetyl-beta-D-hexosaminidase (HEX-B) cuts through the protective outer sugar layer of the egg during fertilization. A decoy sugar molecule that mimics the natural egg coating is being investigated. The synthetic sugar would bind specifically to sperm HEX-B enzyme, curtailing the sperm's ability to penetrate the egg's outer coating. Related experiments in male rats have shown effective and reversible contraceptive properties.

Perhaps one of the most researched methods of male contraception using drugs involves the use of hormones. Like female contraceptive pills, Male Hormone Contraceptives (MHCs) seek to stop the production of sperm by stopping the production of hormones that direct the development of sperm. Many hormones in the human body work by feedback mechanisms. When levels of one hormone are low, another hormone is released that results in an increase in the first. The goal of MHCs is to artificially raise the levels of hormone that would result in suppression of hormone release required for sperm production. The best MHC produced only provides about 90% sperm suppression, which is not enough to reliably prevent conception. Also, for poorly understood reasons, some men do not respond to the MHC preparations under investigation. Despite initial promise, more research is needed to make MHCs competitive with female contraception. Response failure rates for current MHC drugs range from 5–20%.

Man and the Biosphere Program

The Man and the **Biosphere** (MAB) program is a global system of biosphere reserves begun in 1986 and organized by the United Nations Educational, Social, and Cultural Organization (**UNESCO**). MAB reserves are designed to conserve natural ecosystems and **biodiversity** and to incor-

porate the sustainable use of natural ecosystems by humans in their operation. The intention is that local human needs will be met in ways compatible with resource **conservation**. Furthermore, if local people benefit from tourism and the harvesting of surplus **wildlife**, they will be more supportive of programs to preserve **wilderness** and protect wildlife.

MAB reserves differ from traditional reserves in a number of ways. Instead of a single boundary separating **nature** inside from people outside, MAB reserves are zoned into concentric rings consisting of a core area, a **buffer** zone, and a transition zone. The core area is strictly managed for wildlife and all human activities are prohibited, except for restricted scientific activity such as **ecosystem** monitoring. Surrounding the core area is the buffer zone, where non-destructive forms of research, education, and tourism are permitted, as well as some human settlements. Sustainable light resource extraction such as **rubber** tapping, collection of nuts, or selective **logging** is permitted in this area. Pre-existing settlements of **indigenous peoples** are also allowed. The transition zone is the outermost area, and here increased human settlements, traditional **land use** by native peoples, experimental research involving ecosystem manipulations, major restoration efforts, and tourism are allowed.

The MAB reserves have been chosen to represent the world's major types of regional ecosystems. Ecologists have identified some 14 types of biomes and 193 types of ecosystems around the world and about two-thirds of these ecosystem types are represented so far in the 276 biosphere reserves now established in 72 countries. MAB reserves are not necessarily pristine wilderness. Many include ecosystems that have been modified or exploited by humans, such as **rangelands**, subsistence farmlands, or areas used for **hunting** and fishing. The concept of biosphere reserves has also been extended to include coastal and marine ecosystems, although in this case the use of core, buffer, and transition areas is inappropriate.

The establishment of a global network of biosphere reserves still faces a number of problems. Many of the MAB reserves are located in debt-burdened developing nations, because many of these countries lie in the biologically rich tropical regions. Such countries often cannot afford to set aside large tracts of land, and they desperately need the short-term cash promised by the immediate exploitation of their lands. One response to this problem is the debt for nature swaps in which a conservation organization buys the debt of a nation at a discount rate from banks in exchange for that nation's commitment to establish and protect a nature reserve.

Many reserves are effectively small, isolated islands of natural ecosystems surrounded entirely by developed land. The protected organisms in such islands are liable to suffer genetic **erosion**, and many have argued that a single large reserve would suffer less genetic erosion than several smaller reserves which cumulatively protect the same amount of land. It has also been suggested that reserves sited as close to each other as possible, and corridors that allow movement between them, would increase the **habitat** and **gene pool** available to most **species**.

Manatees

A relative of the elephant, manatees are totally aquatic, herbivorous mammals of the family Trichechidae. This group arose 15–20 million years ago during the Miocene period, a time which also favored the development of a tremendous diversity of aquatic plants along the coast of South America. Manatees are adapted to both marine and freshwater habitats and are divided into three distinct **species**: the Amazonian manatee (*Trichechus inunguis*), restricted to the freshwaters of the Amazon River; the West African manatee (*Trichechus senegalensis*), found in the coastal waters from Senegal to Angola; and the West Indian manatee (*Trichechus manatus*), ranging from the northern South American coast through the Caribbean to the southeastern coastal waters of the United States. Two other species, the dugong (*Dugong dugon*) and Steller's sea cow (*Hydrodamalis gigas*), along with the manatees, make up the order Sirenia. Steller's sea cow is now extinct, having been exterminated by man in the mid-1700s for food.

These animals can weigh 1,000–1,500 lb (454–680 kg) and grow to be more than 12 ft (3.7 m) long. Manatees are unique among aquatic mammals because of their herbivorous diet. They are non-ruminants, therefore, unlike cows and sheep, they do not have a chambered stomach. They do have, however, extremely long intestines (up to 150 ft/46 m) that contain a paired blind sac where bacterial digestion of cellulose takes place. Other unique traits of the manatee include horizontal replacement of molar teeth and the presence of only six cervical, or neck, vertebrae, instead of seven as in all other mammals. The intestinal sac and tooth replacement are adaptations designed to counteract the defenses evolved by the plants that the manatees eat. Several plant

Manatee with a researcher, Homosassa Springs, Florida. (Photograph by Faulkner. Photo Researchers Inc. Reproduced by permission.)

species contain tannins, oxalates, and **nitrates**, which are toxic, but which may be detoxified in the manatee's intestine. Other plant species contain silica spicules, which, due to their abrasiveness, wear down the manatee's teeth, necessitating the need for tooth replacement. The life span of manatees is long, greater than 30 years, but their reproductive rate is low, with gestation being 13 months and females giving birth to one calf every two years. Because of this the potential for increasing the population is low, thus leaving the population vulnerable to environmental problems.

Competition for food is not a problem. In contrast to terrestrial herbivores, which have a complex division of food resources and competition for the high-energy level land plants, manatees have limited competition from **sea turtles**. This is minimized by different feeding strategies employed within the two groups. Sea turtles eat blades of seagrasses at greater depths than manatees feed, and manatees tend to eat not only the blades, but also the rhizomes of these plants, which contain more energy for the warm-blooded mammals.

Because manatees are docile creatures and a source of food, they have been exploited by man to the point of **extinction**. There are currently between 1,500 and 3,000 in the U.S. Also because manatees are slow moving, a more recent threat is taking its toll on these shallow-swimming animals. Power boat propellers have struck hundreds of manatees in recent years, causing 90% of the man-related manatee deaths. This has also resulted in permanent injury or scarring to others. **Conservation** efforts, such as the **Marine Mammals Protection Act** of 1972 and the **Endangered Species Act** of 1973, have helped reduce some of these problems but much more will have to be done to prevent the extirpation of the manatees.

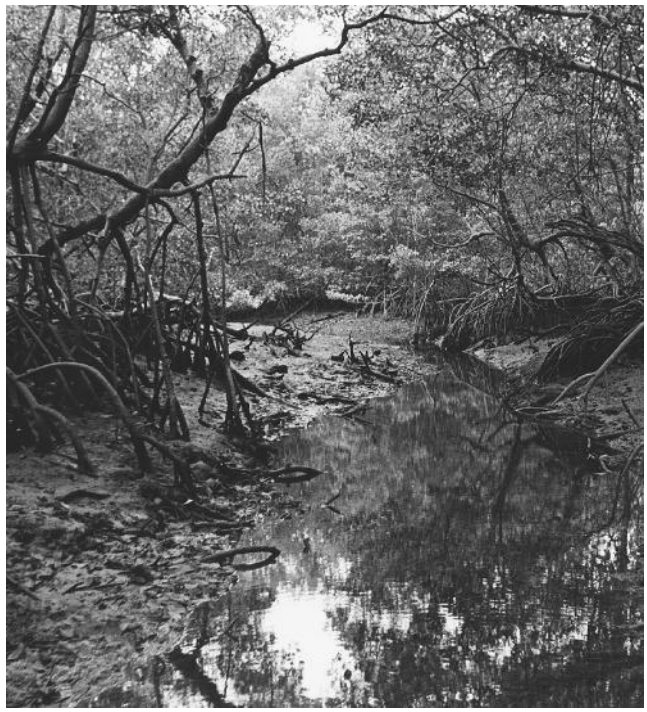
Mangrove swamp



Mangrove swamps or forests are the tropical equivalent of temperate salt marshes. They grow in protected coastal embayments in tropical and subtropical areas around the world, and some scientists estimate that 60-75 percent of all tropical shores are populated by mangroves.

The term "mangrove" refers to individual trees or shrubs that are angiosperms (flowering plants) and belong to more than 80 **species** within 12 genera and five families. Though unrelated taxonomically, they share some common characteristics. Mangroves only grow in areas with minimal wave action, high **salinity**, and low **soil** oxygen. All of the trees have shallow roots, form pure stands, and have adapted to the harsh **environment** in which they grow. The mangrove swamp or forest community as a whole is called a mangal.

Mangroves typically grow in a sequence of zones from seaward to landward. This zonation is most highly pronounced in the Indo-Pacific regions, where 30-40 species of mangroves grow. Starting from the shore-line and moving inland, the sequence of genera there is *Avicennia* followed by *Rhizophora*, *Bruguiera*, and finally *Ceriops*. In the Caribbean, including Florida, only three species of trees normally grow: red mangroves (*Rhizophora mangle*) represent the pioneer species growing on the water's edge, black mangroves (*Avicennia germinans*) are next, and white mangroves (*Laguncularia racemosa*) grow mostly inland. In addition, buttonwood (*Conocarpus erectus*) often grows between the white mangroves and the terrestrial vegetation.

Mangrove trees have made special adaptations to live in this environment. Red mangroves form stilt-like prop roots that allow them to grow at the shoreline in water up to several feet deep. Like cacti, they have thick succulent leaves which store water and help prevent loss of moisture. They also produce seeds which germinate directly on the tree, then drop into the water, growing into a long, thin seedling known as a "sea pencil." These seedlings are denser at one end and thus float with the heavier hydrophilic (water-loving) end down. When the seedlings reach shore, they take root and grow. One acre of red mangroves can produce three tons of seeds per year, and the seeds can survive floating on the ocean for more than 12 months. Black mangroves produce straw-like roots called pneumatophores which protrude out of the **sediment**, thus enabling them to take oxygen out of the air instead of the **anaerobic** sediments. Both white and black mangroves have salt glands at the base of their leaves which help in the regulation of osmotic pressure.

Mangrove swamps are important to humans for several reasons. They provide water-resistant wood used in construction, charcoal, medicines, and dyes. The mass of prop roots at the shoreline also provides an important **habitat** for a rich assortment of organisms, such as snails, barnacles, oysters, crabs, periwinkles, jellyfish, tunicates, and many species of fish. One group of these fish, called mud skippers (*Periophthalmus*), have large bulging eyes, seem to skip over the mud, and crawl up on the prop roots to catch insects and crabs. Birds such as egrets and herons feed in these productive waters and nest in the tree branches. Prop roots tend to trap sediment and can thus form new land with young mangroves. Scientists reported a growth rate of 656 feet (200 m) per year in one area near Java. These coastal forests can be helpful **buffer** zones to strong storms.

Mangrove creek in the Everglades National Park. (Photograph by Max & Bea Hunn. Visuals Unlimited. Reproduced by permission.)

Despite their importance, mangrove swamps are fragile ecosystems whose ecological importance is commonly unrecognized. They are being adversely affected worldwide by increased **pollution**, use of herbicides, filling, **dredging**, channelizing, and **logging**. *See also* Marine pollution; Wetlands

Marasmus

A severe deficiency of all nutrients, categorized along with other protein energy malnutrition disorders. Marasmus, which means "to waste" can occur at any age but is most commonly found in neonates (children under one year old). Starvation resulting from marasmus is a result of protein and carbohydrate deficiencies. In developing countries and impoverished populations, early weaning from breast feeding and over dilution of commercial formulas places neonates at high risk for getting marasmus.

Because of the deficiency in intake of all dietary nutrients, metabolic processes--especially liver functions--are preserved, while growth is severely retarded. Caloric intake is too low to support metabolic activity such as protein synthesis or storage of fat. If the condition is prolonged, muscle tissue wasting will result. Fat wasting and **anemia** are common and severe. Severe vitamin A deficiency commonly results in blindness, although if caught early, this process can be reversed. Death will occur in 40% of children left untreated.

Mariculture

Mariculture is the cultivation and harvest of marine **flora** and **fauna** in a controlled saltwater **environment**. Sometimes called marine fish farming, marine **aquaculture**, or aquatic farming, mariculture involves some degree of human intervention to enhance the quality and/or quantity of a marine harvest. This may be achieved by feeding practices, protection from predators, breeding programs, or other means.

Fish, crustaceans, salt-water plants, and shellfish may be farm raised for bait, fishmeal and fish oil production, scientific research, **biotechnology** development, and repopulating threatened or **endangered species**. Ornamental fish are also sometimes raised by fish farms for commercial sales. The most widespread use of aquaculture, however, is the production of marine life for human food consumption. With seafood consumption steadily rising and **overfishing** of the seas a growing global problem, mariculture has been hailed as a low-cost, high-yield source of animal-derived protein.

According to the Fisheries Department of the United Nations' Food and Agriculture Organization (FAO), over 33 million metric tons of fish and shellfish encompassing 220 different **species** are cultured (or farmed) worldwide, representing an estimated $49 billion in 1999. Pound for pound, China leads the world in aquaculture production with 32.5% of world output. In comparison, the United States is only responsible for 4.4% of global aquaculture output by weight. Just 7% of the total U.S. aquatic production (both farmed and captured resources) is attributable to aquaculture (compared to 62% of China's total aquatic output).

In the United States, Atlantic **salmon** and channel catfish represent the largest segments of aquaculture production (34% and 40%, respectively, in 1997). Though most farmed seafood is consumed domestically, the United States imports over half of its total edible seafood annually, representing a $7 billion annual trade deficit in 2001. The Department of Commerce launched an aquaculture expansion program in 1999 with the goal of increasing domestic seafood supply derived from aquaculture production to $5 billion annually by the year 2025. According to the U.S. Joint Subcommittee on Aquaculture, U.S. aquaculture interests harvested 842 million pounds of product at an estimated value of $987 million in 1999.

To encourage further growth of the U.S. aquaculture industry, the National Aquaculture Act was passed in 1980 (with amendments in 1985 and 1996). The Act established funding and mandated the development of a national aquaculture plan that would encourage "aquaculture activities and programs in both the public and private sectors of the economy; that will result in increased aquacultural production, the coordination of domestic aquaculture efforts, the **conservation** and enhancement of aquatic resources, the creation of new industries and job opportunities, and other national benefits."

In the United States, aquaculture is regulated by the **U.S. Department of Agriculture** (USDA) and the Department of Commerce through the National Marine Fisheries Service (NMFS), **National Oceanic and Atmospheric Administration** (NOAA). State and local authorities may also have some input into the location and practices of mariculture facilities if they are located within an area governed by a Coastal Zone Management Plan (CZMP). Coastal Zone Management Plans, as authorized by the **Coastal Zone**

Management Act (CZMA) of 1972, allow individual states to determine the appropriate use and development of their respective coastal zones. Subsequent amendments to the CZMA have also made provision for states to be eligible for federal funding for the creation of state plans, procedures, and regulations for mariculture activities in the coastal zone.

Tilapia, catfish, striped bass, yellow perch, walleye, salmon, and trout are just a few of the fresh and salt-water finned fish species farmed in the United States. Crawfish, shrimp, and shellfish are also cultured in the U.S. Some shellfish, such as oysters, mussels, and clams, are "planted" as juveniles and farmed to maturity, when they are harvested and sold. Shellfish farmers buy the juvenile shellfish (known as "spat") from shellfish hatcheries and nurseries. Oysters and mussels are attached to lines or nets and put in a controlled ocean environment, while clams are buried in the beach or in sandy substrate below low tide. All three of these shellfish species feed on **plankton** from salt water.

But just as overfarming takes a toll on terrestrial **natural resources**, aquaculture without appropriate environmental management can damage native ecosystems. Farmed fish are raised in open-flow pens and nets. Because large populations of farmed fish are often raised in confined areas, disease spreads easily and rapidly among them. And farmed fish often transmit sea lice and other **parasites** and diseases to wild fish, wiping out or crippling native stock. Organic **pollution** from **effluent**, the waste products from farmed fish, can build up and suffocate marine life on the sea floor below farming pens. This waste includes fish feces, which contributes to **nutrient loading**, and **chemicals** and drugs used to keep the fish disease free and promote growth. It also contains excess fish food, which often contains dyes to make farmed fish flesh more aesthetically analogous to its wild counterparts.

Farmed fish that escape from their pens interbreed with wild fish and weaken the genetic line of the native stock. If escaped fish are diseased, they can trigger outbreaks among indigenous marine life. Infectious Salmon **Anemia**, a viral disease that has plagued fish farms in New Brunswick and Scotland in the 1990s, was eventually found in native salmon. In 2001, the disease first appeared at U.S. Atlantic salmon farms off the coast of Maine.

The use of drugs in farmed fish and shellfish intended for human consumption is regulated by the U.S. **Food and Drug Administration** (FDA). In recent years, **antibiotic resistance** has been a growing issue in aquaculture, as fish have been treated with a wide array of human and veterinary antibiotic drugs to prevent disease.

The commercial development of genetically-engineered, or transgenic, farmed fish is also regulated by FDA. As of May 2002, no transgenic fish had been cleared by FDA for human consumption. The impact transgenic fish may have on the survival and reproduction of native species will have to be closely followed if and when commercial farming begins.

As mandated by the 1938 Mitchell Act, the NMFS funds 25 salmon hatcheries in the Columbia River Basin of the Pacific Northwest, the largest federal marine fishery program in the United States. These aquaculture facilities were originally introduced to assist in repopulation of salmon stocks that had been lost to or severely hampered by hydroelectric dam projects. However, some environmentalists charge that the salmon hatcheries may actually be endangering wild salmon further, by competing for local **habitat** and weakening the genetic line of native species.

Without careful resource management, aquaculture may eventually take an irreversible toll on other non-farmed marine species. Small pelagic fish, such as herring, anchovy, and chub, are captured and processed into fish food compounds for high-density carnivorous fish farms. According to the FAO, at its current rate, fish farming is consuming twice as many wild fish in feeding their domestic counterparts as aquaculture is producing in fish harvests—an average of 1.9 kg of wild fish required for every kilogram of fish farmed.

No matter how economically sound mariculture has been, it has also led to serious habitat modification and destruction, especially in mangrove forests. In the past twenty years, the area of mangrove forests have dwindled by 35% worldwide. Though some of that loss is due to active **herbicide** control of mangroves, their conversion to salt flats, and the industrial harvesting of forest products (wood chips and lumber), mariculture is responsible for 52% of the world's mangrove losses.

Mangrove forests are important to the environment because these ecosystems are **buffer** zones between saltwater areas and freshwater/land areas. Mangroves act as **filters** for agricultural nutrients and pollutants, **trapping** these contaminants before they reach the deeper waters of the ocean. They also prevent coastal **erosion**, provide spawning and nursery areas for fish and shellfish, host a variety of migratory **wildlife** (birds, fish, and mammals), and support habitats for a number of endangered species.

Shrimp farming, in particular, has played a major role in mangrove forest reduction. Increasing from 3% to 30% in less than 15 years, commercial shrimp farming has impacted coastal mangroves profoundly by cutting down mangrove trees to create shrimp and prawn ponds. In the Philippines, 50% of the mangrove environments were converted to ponds and between 50% and 80% of those in Southeast Asia were lost to pond culture as well.

Shrimp mariculture places high demands on resources. It requires large supplies of juvenile shrimp, which can seriously deplete natural shrimp stocks, and large quantities of

shrimp meal to feed them. There also is considerable waste derived from shrimp production. This can pump organic matter and nutrients into the ponds, causing eutrophication, which causes algae bloom and oxygen depletion in the ponds themselves or even downstream. Many shrimp farmers need to pump pesticides, fungicides, parasiticides, and algicides into the ponds between harvests to sterilize them and mitigate the effects of nutrient loading. Shrimp ponds also have extremely short life spans, usually about 5–10 years, forcing their abandonment and the cutting of more mangrove forests to create new ponds.

Mariculture also limits other marine activities along coastal waters. Some aquaculture facilities can occupy large expanses of ocean along beaches which become commercial and recreational no-fish zones. These nursery areas are also sensitive to disturbances by recreational activities like boating or swimming and the introduction of pathogens by domestic or farm animals.

Marine ecology and biodiversity

Understanding the nature of ocean life and the patterns of its diversity represents a difficult challenge. Not only are there technical difficulties involved with studying life under water (high pressure, need for oxygen tanks, lack of light), there is an urgency to develop a greater understanding of marine life as links between ocean processes and the larger patterns of terrestrial life become more well known. Our current understanding of oceanic life is based on three principal concepts: size, complexity, and spatial distribution.

Our knowledge about the size of the ocean's domain is grounded in three great discoveries of the past few centuries. When Magellan first circumnavigated the earth he inadvertently found that the oceans were a continuous water body, rather than a series of discrete bodies of water. Some time later, the encompassing nature of the world oceans was further clarified by the discovery that the oceans were a chemically uniform aqueous system. All of the principal ions (sodium, chloride, and sulfate) exist in the same concentrations. The third discovery, still underway, is that the ocean is composed of comparatively immense ecological systems. Thus in most ways the oceans are a unified system which is the first defining characteristic of the marine **environment**.

There is, however, a dichotomy between the integral nature of the ocean and the external forces played upon it. Mechanical, thermodynamic, chemical, and biological forces create variation through such things as differential heating, Coriolis force, wind, dissolved gases, **salinity** differences, and evaporation. The actions in turn set controls in motion which move toward physical equilibrium through feedback mechanisms. Those physical changes then interact with biological systems in nonlinear ways, that is, out of synchronization with the external stimuli and become quite difficult to predict. Thus, we have the second broad characteristic of the oceans, complexity.

The third major aspect of ocean life is that life itself is sparse in terms of the overall volume of the oceans, but locally productive systems can create immense populations and/or sites with exceptionally high **species** diversity. Life is arranged in active layers dictated by nutrients and light in the horizontal planes, and by vertical current (downwelling and upwelling) in the vertical planes. Life decreases through the depth zones from the epipelagic zone in the initial 328 ft (100 m) of the water column to the bottom layers of water, and then jumps again at the benthic layer at the water-substrate interface. Life also decreases from the littoral zones along the world's shorelines to the open ocean, interrupted by certain areas with special life supporting systems, like floating sargasso weed beds.

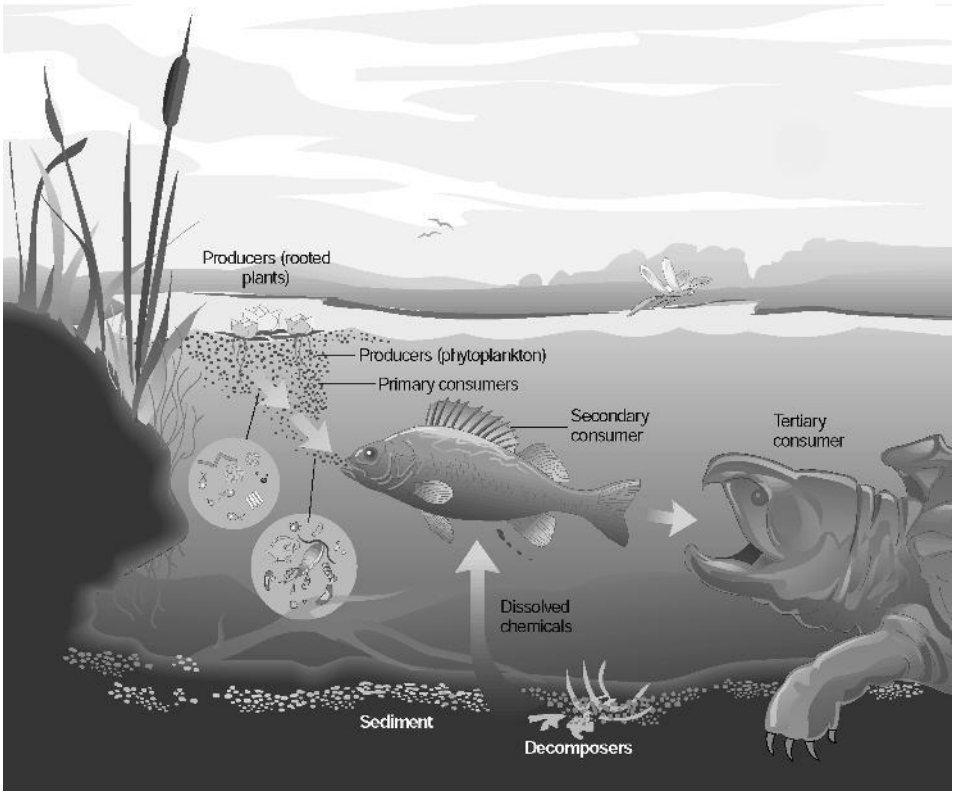
In the past twenty years the focus of **conservation** has shifted to include not only individual species or habitats,

but to a phenomenon called biological diversity, or **biodiversity** for short. Biological diversity encompasses from three to four levels. Genetic diversity is the level of genotypic differences within all the individuals that constitute a population of organisms; species diversity refers to the number of species in an area; and community diversity to the number of different community types in a landscape. The highest level, landscape diversity has not frequently been applied in aqueous environments and will not be discussed here.

Commonly, species diversity is interpreted as biological diversity, and since few marine groups, except marine mammals, have had very much genetic work done, and community functions are only well known from a few systems, it is the taxonomic interpretation of diversity that is most commonly discussed (e.g., species or higher taxonomic levels such as families and classes, orders and phyla). Of all the species that we know, roughly 16% are from the seas. General diversity patterns in the sea are similar to those on land, there are more smaller than larger species, and there are more tropical species than temperate or polar species. There are centers of diversity for specific taxa, and the structure of communities and ecosystems is based on particular patterns of energy availability. For example, **estuary** systems are productive due to importation of **nitrogen** from the land, coral reefs are also productive, but use scarce nutrients efficiently by specially adapted filter feeding mechanisms. Abyssal communities, on the other hand, depend on their entire energy supply from **detritus** fall from upper levels in the ocean. Perhaps the most specifically adapted of all life forms are the hydrothermal vent communities that employ **chemosynthesis** rather than **photosynthesis** for primary production. Water temperature, salinity, and pressure create differing ecosystems in ways that are distinctly different from terrestrial systems. In addition, the boundaries between systems may be dynamic, and are certainly more difficult to detect than on land.

Most marine biodiversity occurs at higher taxonomic levels, while the land holds more species, most of them are arthropods. Most of the phyla (32 of 33) that we now know are either marine, or both marine and non-marine, while only one is exclusively non-marine. Thus most of the major life plans exist in the sea.

We are now learning that the number of species in the ocean is probably underestimated as we discover more cryptic species, very similar organisms that are actually distinct, many of which have been discovered on the deep ocean floor. This is one of the important diversity issues in the marine environment. Originally, the depths were cast as biological deserts, however, that view may have been promoted by a lack of samples, the small size of many benthic invertebrates, and the low density of benthic populations in the deep sea beds.



Improved sampling since the 1960s changed that view to one of the ocean floor as a highly species diverse environment. The deep sea is characterized by a few individuals in each of many species; rarity dominates. Whereas, in shallow water benthic environments, there are large, dense populations dominated by a few species. At least three theoretical explanations for this pattern have been made. The stability-time hypothesis suggests that ocean bottoms have been very stable environments over long periods of time. This condition causes very finely tuned adaptations to narrow niches, and results in many closely related species. The disturbance or "cropper" hypothesis suggests that intense predation of limited food sources prevents populations from reaching high levels and because the food source is dominated by detrital rain, generalist feeders abound and compete for the same food, which results in only small differences between species. A third hypothesis is that the area of the deep sea bed is so large it supports many species, following from generalizations made by the species area relationship concept used in **island biogeography** theory. The picture of species number and relative rarity is still not clearly understood.

In general, some aspects of marine biology are well studied. Rocky intertidal life has been the subject of major ecological research and yielded important theoretical advances. Similarly, coral reefs are the subject of many studies of life history **adaptation** and evolutionary biology and **ecology**. Physiology and morphology research has used many marine animals as examples of organisms' functions under extreme conditions. This new found knowledge is timely. Up until now we have considered the oceans as an inexhaustible source of food and a sink for our wastes, yet we now realize they are neither. Relative to the land, the sea is in good ecological condition, but to prevent major ecological problems in the marine environment we need to increase human knowledge rapidly and manage our behavior toward the oceans very conservatively, which is a difficult task under the conditions where the ocean is treated as a common resource.

[*David Duffus*]

Marine Mammals Protection Act (1972)

The Marine Mammals Protection Act (MMPA) was initially passed by Congress in 1972 and is the most comprehensive federal law aimed at the protection of marine mammals. The MMPA prohibits the taking (i.e., harassing, **hunting**, capturing, or killing, or attempting to harass, hunt, capture, or kill) on the high seas of any marine mammal by persons or vessels subject to the jurisdiction of the United States. It also prohibits the taking of marine mammals in

An example of a marine ecosystem. (Illustration by Hans & Cassidy.)

waters or on land subject to United States jurisdiction and the importation into the United States of marine mammals, parts thereof, or products made from such animals. The MMPA provides that civil and criminal penalties apply to illegal **takings**.

The MMPA specifically charges the National Marine Fisheries Service (NMFS) with responsibility for the protection and **conservation** of marine mammals. The NMFS is given statutory authority to grant or deny permits to take **whales**, **dolphins**, and other mammals from the oceans.

The original legislation established "a moratorium on the taking of marine mammals and marine mammal products...during which time no permit may be issued for the taking of any marine mammal and no marine mammal may be imported into the United States." Four types of exceptions allowed for limited numbers of marine mammals to be taken: (1) animals taken for scientific review and public display, after a specified review process; (2) marine mammals taken incidentally to **commercial fishing** operations prior to October 21, 1974; (3) animals taken by Native Americans and Inuit Eskimos for subsistence or for the production of traditional crafts or tools; and (4) animals taken under a temporary exemption granted to persons who could demonstrate economic hardship as a result of MMPA (this exemption was to last for no more than a year and was to be eliminated in 1974). MMPA also sought specifically to reduce the number of marine mammals killed in purse-seine or drift net operations by the commercial tuna industry.

The language used in the legislation is particularly notable in that it makes clear that the MMPA is intended to protect marine mammals and their supporting **ecosystem**, rather than to maintain or increase commercial harvests: "[T]he primary objective in management should be to maintain the health and **stability** of the marine ecosystem. Whenever consistent with this primary objective, it should be the goal to obtain an optimum sustainable population keeping in mind the optimum **carrying capacity** of the habitat."

All regulations governing the taking of marine mammals must take these considerations into account. Permits require a full public hearing process with the opportunity for judicial review for both the applicant and any person opposed to the permit. No permits may be issued for the taking or importation of a pregnant or nursing female, for

taking in an inhumane manner, or for taking animals on the **endangered species** list.

Subsidiary legislation and several court decisions have modified, upheld, and extended the original MMPA: *Globe Fur Dyeing Corporation v. United States* upheld the constitutionality of the statutory prohibition of the killing of marine mammals less than eight months of age or while still nursing.

In *Committee for Humane Legislation v. Richardson*, the District of Columbia Court of Appeals ruled that the NMFS had violated MMPA by permitting tuna fishermen to use the purse-seine or drift net method for catching yellowfin tuna, which resulted in the drowning of hundreds of thousands of porpoises.

Under the influence of the Reagan Administration, MMPA was amended in 1981 specifically to allow this type of fishing, provided that the fishermen employed "the best marine mammal safety techniques and equipment that are economically and technologically practicable." The Secretaries of Commerce and the Interior were empowered to authorize the taking of small numbers of marine mammals, provided that the **species** or population stocks of the animals involved were not already depleted and that either Secretary found that the total of such taking would have a negligible impact.

The 1984 reauthorization of MMPA continued the tuna industry's general permit to kill incidentally up to 20,500 porpoises per year, but provided special protection for two threatened species. The new legislation also required that yellowfin tuna could only be imported from countries that have rules at least as protective of porpoises as those of the United States.

In *Jones v. Gordon* (1985), a federal district court in Alaska ruled in effect that the **National Environmental Policy Act** provided regulations which were applicable to the MMPA permitting procedure. Significantly, this decision made an **environmental impact statement** mandatory prior to the granting of a permit.

Presumably owing to the educational, organizing, and lobbying efforts of environmental groups and the resulting public outcry, the MMPA was amended in 1988 to provide a three-year suspension of the "incidental take" permits, so that more ecologically responsible standards could be developed. Subsequently, Congress decided to prohibit the drift netting method as of the 1990 season.

In 1994, the MMPA was amended to include more concrete definitions of harassment levels and grouped them as level A harassment (potential to hurt a wild marine mammal) and level B harassment (potential to disrupt their **environment** or biology). The 1994 amendments also constructed new restrictions of photography permits and states under harassment level B that scientific research must limit its influence on the marine mammals being studied.

Marine pollution

Marine **pollution** is a major threat to any organism living in or depending upon the ocean. Human impact on coastal and open ocean habitats comes in many forms: **nutrient loading** from agricultural **runoff** and sewage discharges, toxic chemical inputs from industry and agriculture, **petroleum** spills, and inert solid wastes. While there has been some recognition of the destruction of marine systems from pollution, regulations are often weak or are not enforced. Recent efforts have lead to slow recovery of some coastal areas, but many of the detrimental practices continue and some systems may never recover.

Nutrient loading is perhaps the most well-studied form of pollution, and its biological consequences have been observed and documented. Algal blooms, including red tides, have been attributed to elevated nutrient levels in coastal systems. These blooms, through their **respiration** and **decomposition**, can deplete the levels of **dissolved oxygen** in the waters to almost zero, killing **zooplankton**, fish, and shellfish. These nutrients often come from runoff of agricultural fertilizers, the use of which has increased sevenfold since 1950. It is estimated that approximately 25 percent of the 46.8 million metric tons of **fertilizer** used in the United States annually enters rivers and coastal waters.

Another source of nutrients is the **discharge** of sewage. The United States and England are the only countries that dump **sludge** into the oceans, averaging 17 million metric tons annually between them. Throughout the world, however, raw sewage is released into rivers and coastal habitats by many countries, leading to algal blooms and increased **biochemical oxygen demand**. BOD, the rate at which oxygen disappears from a sample of water, increases dramati-

cally with loading of organic material such as sewage, and results in the lowering of dissolved oxygen levels. The wastes of domesticated animals may also have a major impact in some systems. A single cow produces approximately 31 lb (14 kg) of waste per day, the equivalent of ten people. When discharged into rivers or coastal waters, wastes produced by large herds or **feedlots** may have substantial effects.

Boston Harbor is considered to be one of the most polluted harbors in the United States. Since Europeans settled in the Boston area, domestic wastes have been discharged directly into the harbor. As Boston's population grew, so did the dumping, a problem exacerbated by the growth of industry in the late nineteenth and early twentieth centuries. Fish and shellfish in the harbor contain toxic levels of polychlorinated biphenyl (PCB) and **heavy metals**, BOD levels are astronomical, and dissolved oxygen levels are low. In 1984, the Massachusetts **Water Resources** Authority (MWRA) was formed and has managed to improve **water quality** of the harbor slightly. Recommendations of the MWRA have been hard to enact, however. **Sewage treatment** modifications have been met with **Environmental Protection Agency** (EPA) and State objections, shelving the project while courts decide the fate of environmental quality in Boston Harbor.

Toxic substances are introduced into the marine **environment** from various sources, some of which may be hundreds of kilometers away. Heavy metals, pesticides, and **acid rain** threaten not only coastal and estuarine systems, but also life in the open ocean. Heavy metals occur in many forms, some of which are soluble in seawater. These soluble compounds may not be the forms in which they were originally released into the environment, often making their sources difficult to determine. Many heavy metals are released in industrial effluents, especially from chemical plants, smelters, and mining runoff. These compounds may affect humans directly through contact, or indirectly, from the consumption of fish and shellfish, where metals often accumulate in tissues.

Between the late 1930s and the mid-1950s, a Japanese chemical company manufacturing acetaldehyde discharged **mercury** into Minamata Bay, where it formed a soluble compound that accumulated in fish. It was not until 50 people died of **Minamata disease** and hundreds were left with debilitating nervous disorders from eating poisoned fish that environmental studies were initiated. Finally, in 1969, the plant was closed. Other metals, such as zinc, **cadmium**, **copper**, and silver, are commonly discharged into marine systems by industry. Not only are these metals toxic by themselves, but synergistic effects compound their toxicity.

Acid precipitation is rain, snow, or fog that has a lower **pH** than normal and is caused by inputs of nitric and sulfuric acid into the **atmosphere** from manufacturing and the burning of **fossil fuels**, as in automobiles. These causes may be far from the area of impact since prevailing winds can carry pollutants considerable distances. The ocean has a high **buffer** capacity, that is, the ability to neutralize many of the acid inputs. Therefore, most of the severe effects of acid rain are observed in freshwater lakes and rivers. Some estuaries, however, may also be seriously impacted, as has been observed in the upper **Chesapeake Bay**. The pH of a river feeding the Bay dropped from 6.3 to 5.8 between 1972 and 1978. Juvenile and spawning striped bass may not be able to tolerate such high acidity. Precipitation of nitrogen-based acid also increases nutrient loading in aquatic systems.

Toxic organic compounds, especially pesticides and a family of **chemicals** known as PCBs, have been shown to have serious effects on marine systems. Runoff has introduced considerable amounts of PCBs, DDT, and many other synthetic organic compounds into coastal areas. These compounds may persist for many years. In 1976, Congress banned the manufacture of PCBs, but they are still found today as coolants in older transformers and buried in sediments. It is estimated that 1 percent of PCBs used have reached the ocean. In 1987–1988, 700 bottlenose **dolphins** washed up on the U.S. Atlantic coast and some were found to have elevated levels of PCBs and DDE (a form of DDT). Biologists claim that these compounds inhibited the dolphins' immune systems, making them vulnerable to infections. In 1975, workers at a chemical plant on the Chesapeake were poisoned when the insecticide **Kepone** was leaked or dumped into the bay. The Kepone spread downstream where it poisoned fish and shellfish.

One of the most publicized sources of marine pollution is that caused by petroleum products. While large **oil spills** can devastate a local area, equally important is the discharge of crude oil while cleaning bilges and emptying tanks at sea. Over the past decade, an average of approximately 32 million gallons (120 million l) of oil have been spilled annually. The Gulf of Mexico has recorded the most spills, while spills in the Persian Gulf average 2 million gallons (7 million l) per year. Since tanker ports and refineries are, by necessity, located on the coast, these sensitive areas receive considerable damage from the spills. The damage to marine life is staggering. Seabirds are killed by the hundreds of thousands annually, their oil-matted plumage making flight impossible and exposing them to hypothermia. Oil-soaked fur of marine mammals loses its water repellency, also leading to death by hypothermia. Ingestion of oil by fishes, birds, and mammals also may result in death.

Hundreds of tons of inert solid wastes are dumped into the oceans from ships annually. Of these, **plastics** and **polystyrene** (styrofoam) are deadly to marine life. Often floating for hundreds of miles and lasting for many years, plastics are frequently mistaken for food by fishes, turtles,

and mammals, and proceed to either interfere with subsequent feeding or strangle the consumer. It has been estimated that plastics and discarded fishing gear, such as monofilament line and discarded nets, kill one million seabirds and 150,000 marine mammals each year.

Beginning with the Refuse Act of 1899 and the **Water Pollution** Act of 1948, there have been efforts to remedy the polluted oceans. Not until 1972, however, was legislation drafted that was powerful enough, and sufficient monies appropriated, to effect any change. With the Federal Water Pollution Act, or **Clean Water Act**, improvement of water quality in the United States began. By 1985, five of the goals of the 1972 Act were reached, and since then, the Clean Water Act has been rewritten to reflect increasing national concerns.

Pollution of the world's oceans had become so pervasive that an international convention was convened in 1973 to establish laws governing the discharge of all wastes into the ocean. The International Convention for the Prevention of Pollution from Ships (1978), commonly known as MARPOL, and subsequent annexes to the convention, covers all **garbage** discharged by ships at sea beyond three miles from shore. While it is too soon to tell, adherence to the MARPOL agreement should significantly reduce the amount of solid wastes polluting the world's oceans.

Boston Harbor, the Chesapeake Bay, and the **Mediterranean Sea** are the most publicized examples of marine pollution. However, the problem is widespread. Many estuaries in Southeast Asia, many coastal areas in Japan, and the waters off Rio de Janeiro are also areas where historical and current use of the waters as dumping grounds has left them in disastrous conditions. The Golden Horn estuary around Istanbul, Turkey, has been declared dead, containing no living organisms and posing a threat to surrounding waters at the eastern end of the Mediterranean.

Since humans have been living along the coasts and using the seas as waste dumping grounds for thousands of years, these areas are the most heavily impacted. What makes matters worse is that coastal waters are vital spawning and nursery grounds for most of the commercially harvested fish and shellfish in marine systems. Destruction of these areas has significant nutritional and economic repercussions. Examples of the world-wide destruction of marine habitats due to pollution are numerous, but, with increased international efforts to limit inputs and rehabilitate damaged areas, improvements in the health of marine systems may be seen. *See also* Bioaccumulation; Estuary; Food chain/web; Heavy metals and heavy metal poisoning

Marine protected areas

Marine protected areas (MPAs)are marine environments that enjoy certain federal, state, local, or tribal regulation and **conservation** management programs by virtue of their unique ecosystems and/or cultural resources.

Known variously as marine reserves, marine sanctuaries, and/or no- take areas, marine protected areas may include national marine sanctuaries, marine features of national parks and monuments, marine **wildlife** refuges, fishery reserves, estuarine reserves, or state conservation areas and reserves. They may be regulated as no-take areas, meaning that marine resources and/or marine life cannot be removed from these sanctuaries. Or, they may allow fishing and other commercial or recreational activities within certain guidelines and limitations. Management of an MPA is determined on a site-by-site basis by one or more federal, state, territorial, local, and/or tribal regulatory authorities.

Marine protected areas are not just a reaction to the effects of industrialization. They have existed in some form among traditional fishing cultures for centuries. Tabu or kapu areas, controlled by clans or chiefs in Oceania, created no-take zones. When westernization occurred, many of these areas disappeared. In recent years, some of these tabu areas have been revived.

Some countries created protected areas along their coastlines through governmental decrees or legislation. The Royal **National Park** in New South Wales, **Australia**, is perhaps the oldest protected area in the world. Designated in 1879, the park prohibits the use of explosives, net-fishing, and the commercial harvesting of oysters. Certain areas restrict all **commercial fishing**. Other Australian reserves followed. Today, another Australian MPA, the **Great Barrier Reef** Marine Park, is considered one of the most successful multiple-use MPAs in the world.

Other governments soon instituted marine protected areas on their shores. New Zealand has led the world with the establishment of 291 MPAs. Africa has established 92 reserves, and Europe is rapidly catching up, with MPAs popping up in France, Spain, Greece, Albania, Bosnia, and Croatia.

Though the United States has 9,3208 mi.(150,000 km) of coastline and had some initial legislation in place, it waited until serious damage was occurring before developing a viable plan to coordinate the nation's MPA-related initiatives. Unfortunately, much of the focus of the US MPAs will first be on remediaton of many of its fragile coastal environments before concentrating on developing an inclusive plan for its extensive coastline.

In May 2000, President Clinton signed Executive Order 13158 on Marine Protected Areas, which was designed to ensure the long-term security of critical ocean habitats, marine life, and cultural resources through an integrated national network of science-based MPA selection and management. The order designated the Department of Interior and Department of Commerce as jointly responsible for the MPA mission to "(a) strengthen the management, protection, and conservation of existing marine protected areas and establish new or expanded MPAs; (b) develop a scientifically based, comprehensive national system of MPAs representing diverse U.S. marine ecosystems, and the Nation's natural and cultural resources; and (c) avoid causing harm to MPAs through federally conducted, approved, or funded activities."

Executive Order 13158 mandated the creation of a national database of MPAs. This register of nationally-recognized MPAs would promote integrated conservation efforts between federal, state, and local authorities and stakeholders. Order 13158 defined an MPA as "any area of the marine **environment** that has been reserved by federal, state, territorial, tribal or local laws or regulations to provide lasting protection for part or all of the natural and cultural resources therein." To further hone this relatively broad-based definition, the **National Oceanic and Atmospheric Administration** (NOAA) has established five criteria for inclusion in the MPA inventory:

- The site must have defined geographical boundaries and must be in federal, U.S. territorial, state, or tribal marine areas.
- The site must be marine in **nature**, meaning that it includes ocean or coastal waters, including intertidal areas, bays, and estuaries. It may also be a part of the **Great Lakes** or their connecting waters, and can include land as an integral component of the site.
- Must be established as a reserved area by Federal, state, territorial, local, or tribal law or regulation.
- Must be lasting, as in a permanent and year-round protected area.
- Must have existing laws or regulations that are designed and applied to afford the site with increased protection for part or all of the natural and cultural resources therein.

The MPA list had not yet been developed as of May 2002.

The establishment of a MPA list or inventory would bring further clarity and regulatory integration to a legacy of environmental legislation affecting ocean habitats that began with the National Marine Sanctuaries Act (NMSA) in 1972 (and its amendments and reauthorizations in 1980, 1984, 1988, 1992, 1996, and 2000). NMSA, Title III of the **Marine Protection, Research and Sanctuaries Act**, was signed by President Nixon on the 100-year anniversary of the **National Park Service**. The Act set up the criteria for national sanctuaries that today only include 13 marine areas spanning approximately 18,000 mi^2 (28,967.4 km^2). As of May 2002, U.S. nationally- designated sanctuaries include:

- *Channel Islands.* Designated as a marine sanctuary in 1980, the Channel Islands are located off the coast of Santa Barbara, California. The unique **ecosystem** of the sanctuary is home to giant kelp forests and 27 **species** of **whales** and dolphins.
- *Cordell Bank.* Cordell Bank is a submerged island on the edge of the continental shelf off the coast of San Francisco. The sanctuary, created in 1989, covers 526 mi^2 (846.5 km^2) that are home to a rich and diverse array of marine life.
- *Fagatele Bay.* A tropical **coral reef** formed by a now-extinct **volcano**, Fagatele Bay is located off of Tutuila, an island of American Somoa. The sanctuary was designated in 1986.
- *Florida Keys.* The Florida Keys National Marine Sanctuary encompasses 28,000 nautical mi^2 (51,856 km^2) surrounding the Florida Keys, and includes such unique features as coral reefs and mangroves. It was established in 1990.
- *Flower Garden Banks.* A series of three sites off the coasts of Texas and Louisiana, Flower Garden Banks was established in 1992 and 1996 as a national marine sanctuary (two sites in 1992 and the third in 1996). The area's unique coral reefs and twin salt domes host an abundance of tropical marine life.
- *Gerry E. Studds-Stellwagen Bank National Marine Sanctuary.* This nutrient-rich expanse of Massachusetts Bay is home to the endangered right and humpback whales. It was designated in 1992.
- *Gray's Reef.* Given sanctuary status in 1981 by President Carter, Gray's Reef is a sandstone reef with a "live-bottom habitat"—attached corals, sponges, and other invertebrates. The sanctuary encompasses 17 mi^2 (27.4 km^2) off the coast of Georgia.
- *Gulf of the Farallones.* The 1,255 mi^2 (2,019.7 km^2) Gulf of the Farallones National Marine Sanctuary was created in 1981. Located 30 mi. (48 km) west of San Francisco Bay's Golden Gate Bridge, the Farallones sanctuary is home to a variety of **seals**, **sea lions**, and seabirds.
- *Hawaiian Islands Humpback Whale.* An estimated two-thirds of the entire Pacific humpback whale population

return to the **Hawaiian Islands** in the winter to breed, calve, and raise their young. The sanctuary was designated in 1992 to protect this important **habitat**.

- *Monitor.* The first of only two archaeological sites of the 13 U.S. marine sanctuaries, the Monitor National Marine Sanctuary is the location of the sunken remains of the U.S.S. Monitor, the first ironclad Civil War battleship. The Monitor site was the first U.S. marine sanctuary, designated in 1975 in the coastal waters off North Carolina.
- *Monterey Bay.* Another California coastal sanctuary, Monterey Bay is the largest of the marine sanctuaries at over 5,200 mi^2 (8,368.4 km^2). It was established in 1992.
- *Olympic Coast.* The Olympic Coast National Marine Sanctuary was designated in 1994 and covers 3,300 mi^2 (5,310.7 km^2 off the Washington State coast and Olympic Peninsula. It is home to a rich and complex intertidal ecosystem and a variety of seabirds and marine mammals.
- *Thunder Bay.* Thunder Bay National Marine Sanctuary and Underwater Preserve is the only designated sanctuary located in the Great Lakes. The 448 mi^2 (721 km^2) Lake Huron location, a historical shipping alley, is the site of at least 116 nineteenth and twentieth- century shipwrecks. It became a national sanctuary in 2000.

As of May 2002, NOAA had begun the designation process for a fourteenth national marine sanctuary, the Hawaiian Islands Coral Reef Ecosystem Reserve, home to an estimated 7,000 marine species.

The NMSA calls for marine use management that balances the public's right for appropriate recreational and commercial use of protected areas with habitat conservation and ecosystem needs. Some areas may allow recreational use with permits, or during specific times of the year. Others may restrict certain uses completely. Because human use of marine resources frequently conflicts with **biodiversity** and conservation goals, this is a major challenge of the ongoing management of marine protected areas.

Marine Protection, Research and Sanctuaries Act (1972)

The Marine Protection, Research and Sanctuaries Act of 1972 (also known as the National Marine Sanctuaries Act) is a comprehensive law designed to deal with ocean resources. The law has three main sections: first, it regulates **ocean dumping**; second, it authorizes **marine pollution** research; third, it establishes the marine sanctuary program. These sanctuaries can be established to protect areas of significant **conservation**, cultural, ecological, educational, esthetic, historical, or recreational values. A fourth component to the law, added in 1990, establishes regional marine research programs.

The law established a permit process administered by the **Environmental Protection Agency** (EPA) to regulate all ocean dumping, with the exception of **dredging** materials, which require a permit from the **Army Corps of Engineers**. The act mandated that ocean dumping of sewage **sludge** and industrial waste end by 1981, but this deadline was missed. The **Ocean Dumping Ban Act** of 1988 amended the 1972 law, establishing a deadline of December 31, 1991, for the end of ocean dumping of sewage sludge. A system of escalating fees and fines was incorporated into the act to help reach the deadline. The law also immediately prohibits the dumping of **medical waste** in the ocean

The marine sanctuaries can be designated in coastal waters or in the **Great Lakes**. Thus far, 13 National Marine Sanctuaries have been designated: Channel Islands (off the coast of California), Cordell Bank (California), Fagatele Bay (American Samoa), Florida Keys (Florida), Flower Garden Banks (Louisiana/Texas), Gray's Reef (Georgia), Gulf of the Farallones (California), Humpback Whale (Hawaii), Key Largo (Florida), Looe Key (Florida), Monitor (North Carolina), Monterey Bay (California), and Sellwagen Bank (Massachusetts). Numerous additional sites are being studied for designation. The sanctuaries range in size from the 0.25 mi^2 (0.65 km^2). Fagatele Bay to the 5,312 mi^2 (13,758 km^2) at Monterey Bay (larger than Connecticut).

Designation is usually made by the Secretary of Commerce, after consultation with other agencies and the affected

states' governments. State waters can be included in a sanctuary if the state agrees.

In the 1980s Congress and environmental groups were concerned with the slow pace of sanctuary designation. Congress acted to expedite the designation process, and in 1990 by-passed the usual process completely to designate the Florida Keys Marine Sanctuary, largely in response to a number of ship groundings in the area.

The Sanctuaries and Reserves Division of the **National Oceanic and Atmospheric Administration** (NOAA), in the Department of Commerce, is responsible for the administration of these sanctuaries. Management of the sanctuaries is based on a multiple use approach: the significant resources within the sanctuaries are to be protected, but uses such as diving and sport and **commercial fishing** may also continue in most cases if such uses do not harm the significant resources. Regulations as to what is allowed and not allowed are established for each particular sanctuary, depending on what resources are present and being protected. Offshore gas and **oil drilling**, for example, is not allowed in sanctuaries, but shipping (including oil tankers) often is. In addition to protection and use, the sanctuaries are also sites for research and marine education.

The act has had several amendments added, with the a complete overhaul happening in 1992. Two of those changes were that the management plans of the sanctuaries must be reviewed every five years by the Secretary and the violation fine was raised to $100,000. The most recent amendments were made in 2000. The most significant of those was the clarification of illegal acts on the sanctuaries. *See also* Environmental education; Environmental science; Recreation

Marine provinces

Marine provinces are specific geographic areas of the ocean delineated by common landform (i.e., coastal geology and position of the continental shelf) and water conditions (i.e., temperature, currents, wind patterns, and **salinity**). In addition, marine provinces may be categorized by the unique **flora** and **fauna** (or biota) they support.

With less than five percent of the ocean mapped as of early 2002, the exact number of marine provinces worldwide is unknown. The United States **Geological Survey** (USGS) specifies ten coastal marine and estuarine provinces bordering on the United States—the Acadian, Arctic, Californian, Carolinian, Columbian, Fjord, Louisianian, Pacific Insular, Virginian, and West Indian provinces. The U.S. **Environmental Protection Agency** (EPA) also uses these classifications for its **Environmental Monitoring and Assessment Program** (EMAP), but further divides the Arctic marine province surrounding Alaska into the Arctic, Bering, Aleutian, and Alaskan Provinces.

Marine provinces may be subdivided into marine biogeographical regions or ecoregions. In their classification system for marine ecosystems and habitats, the **National Oceanic and Atmospheric Administration** (NOAA) defines marine provinces as benthic (bottom floor) or pelagic (water column) zones of the ocean. These zones are then categorized by depth (i.e., intertidal, sublittoral, bathyal, abyssal, hadal, neritic, and oceanic) and ocean floor topographical features (e.g., reef, sandbar, crevice, etc.).

Marsh

see **Wetlands**

George Perkins Marshall (1801 – 1882)

American diplomat, philologist, conservationist, politician, and lawyer

A long-time diplomat, Marsh served 21 years as ambassador to Italy and a shorter term in Turkey. He was a skilled lawyer, a Congressman from Vermont, a many-times-failed businessman, a learned scholar, and master of numerous languages. He was also author of *Man and Nature: Physical Geography as Modified by Human Action*, a book that **Gifford Pinchot** called "epoch-making" and that Lewis Mumford, in *The Brown Decades*, described as "the fountainhead of the **conservation** movement." Rene Jules Dubos described Marsh himself as "the first American prophet of ecology" and not a few have ascribed to him the actual founding of the science.

Marsh was born and grew up in Woodstock, Vermont, or as he put it, he was "born in the woods." As a young person, poor eyesight turned him from avid book-worm to student of **nature**, and created his lifelong attitude: "the power most important to cultivate and, at the same time, hardest to acquire, is that of seeing what is before [you]." What he saw, especially in the over-grazed, deforested lands of Italy and Turkey, is what inspired the writing of *Man and Nature*.

The emphasis in Marsh's book is on human beings as agents of change, too often change that is detrimental to nature. "Man is everywhere a disturbing agent. Wherever he plants his foot, the harmonies of nature are turned to discords," he wrote. He went on to emphasize that "not a sod has been turned, not a mattock struck into the ground, without leaving its enduring record of the human toils and aspirations that accompany the act." The consequence of this change, Marsh wrote, is that "the earth is fast becoming an unfit home" for its human inhabitants.

Nevertheless, Marsh was also an early humanist, believing that human dominion over nature could be used constructively: he saw the purpose of his book as not only tracing human ravages of nature, but as also suggesting "the possibility and the importance of the restoration of disturbed harmonies and the material improvements of waste and exhausted regions." His writings and activities spurred others into action.

His reaction to **deforestation** directly influenced the United States Congress to establish a federal forest commission and, eventually, to the reserves now part of the vast system of national forests in the United States. While ambassador to Italy, he wrote a report on **irrigation** for the U.S. Commissioner of Agriculture that led to the formation of the **Bureau of Reclamation** in 1902. His claim that it is "desirable that some large and easily accessible region of American **soil** should remain as far as possible in its primitive condition" influenced **wilderness** advocates such as **John Muir** and **Aldo Leopold** and was an early clarion call for the setting aside of pristine wildlands.

Though not a trained scientist nor a particularly skilled writer, Marsh sensed early the destructive capability and impact of human activities. He assessed those impacts with great clarity and did much to establish a base for intelligent restorative actions.

Robert Marshall (1901 – 1939)

American wilderness advocate

Bob Marshall was the son of a prominent New York lawyer who helped insert the phrase "forever wild" into the state constitution, a key to preserving the forests of the Adirondack region. His experiences in the **Adirondack Mountains** as a youth, at his family's summer place, and the early habit of taking long walks, gave early shape to his preoccupation with the importance of **wilderness**. Marshall worked diligently for the protection of wilderness in the United States for aesthetic reasons and for the psychological health of the American people by counteracting the "drabness" and "horrible banality" of modern civilization.

Marshall earned a forestry degree from Syracuse University, a Masters of Forestry from Harvard, and ultimately a doctorate in plant physiology from Johns Hopkins. He first worked for the United States **Forest Service** at an experimental station in Missoula, Montana, before leaving to continue his education in graduate school. His experience in Montana exposed him to "the working man's" view of forestry, views that conditioned his later opinions on social reform.

The death of his father left him financially independent, but Marshall returned to the Forest Service in 1932

and 1933 to work on the National Plan for American Forestry. He later left to become director of forestry for the Office of Indian Affairs and then returned as chief of the Division of **Recreation** and Lands. In his Indian Affairs position, he worked for a greater role by Native Americans in the management of the forests on their reservations. As head of the Forest Service Division of Recreation and Lands, he became one of the twentieth century's best known voices in support of protection of wilderness areas in national forests. His last achievement may have been the adoption in 1939 of the Regulation U1, governing wilderness areas and Regulation U2 governing wild areas (the two known together as the U Regulations). The Regulations were signed by Agriculture Secretary, Henry Wallace, as a Forest Service policy to endorse the recommendations developed by Marshall (and others on a committee) in an effort to protect these areas from development, including—and especially—road building (but also, **logging**, building, etc.), and to give such areas more permanence by requiring public notice and a waiting period before any alterations.

Bob Marshall's travels to Alaska in the late twenties and thirties resulted in detailed mapping of parts of the Brooks Range. This led in part to their preservation as wilderness and to a better understanding of tree growth at **timberline** in the Arctic.

Two books were written based on his travels to Alaska. The first, *Arctic Village* (1933), based on a year's residence in the Arctic village of Wiseman, earned him wide recognition, both critically and popularly, and was almost an ethnographic study of life among both the Eskimo and the white settlers in the wilderness back country of northern Alaska. The second, *Arctic Wilderness*, published in 1956 (well after his death), was more in line with his well-deserved reputation as a scholar and activist with vast knowledge of wilderness conditions.

Bob Marshall contributed also as one of the founders and financial supporters of the **Wilderness Society**. The Wilderness Society was a culmination of his call for "an organization of spirited people who will fight for the freedom of the wilderness." The Society helped to implement his dream of wilderness preservation through its decisive role in the eventual passage of the **Wilderness Act**, though that did not take place until more than two decades after Marshall's death. The Bob Marshall Wilderness system in Montana was later named in his honor.

Mass burn

Mass burn refers to the **incineration** of unsorted municipal waste in a Municipal Waste Combustor (MWC) or other incinerator designated to burn only waste from municipalities. This **waste management** method avoids the expensive and unpleasant task of sorting through the **garbage** for unburnable materials. All waste received at the facility is shredded into small pieces and fed into the incinerator. Steam produced in the incinerator's boiler can be used to generate electricity or to heat nearby buildings. The residual ash and unburnable materials, representing about 10-20 percent of the original volume of waste, are taken to a **landfill** for disposal. Mass burn incineration also has several drawbacks. Since the waste is unsorted, it often generates more polluting emissions than sorted waste, and it is more likely to corrode burner grates and chimneys. The residual ash and unburned materials may be toxic and require special treatment.

The **Environmental Protection Agency** (EPA) establishes standards for the burning of municipal waste. A MWC is designed so that it cannot burn continuously 24 hours a day. Waste cannot be fed to the unit nor can ash be removed while **combustion** is occurring. As a result, burning occurs in batches or spurts. A large MWC plant has a capacity greater than 250 tons per day. A very large MWC plant has a capacity of about 1,100 tons per day.

Municipal solid waste includes household, commercial or retail, and institutional waste. **Household waste** includes material discarded by single and multiple residential dwellings, hotels, motels, and other similar permanent or temporary housing establishments. Commercial or retail waste includes material discarded by stores, offices, restaurants, warehouses, and nonmanufacturing activities at industrial facilities. Institutional waste includes material discarded by schools, hospitals, and nonmanufacturing activities at prisons, government facilities, and other similar establishments.

Household, commercial or retail, and institutional wastes do not include sewage, wood pallets, construction and demolition wastes, industrial process or manufacturing wastes, or motor vehicles (including motor vehicle parts or vehicle fluff). Municipal **solid waste** also does not include

solely segregated medical wastes. However, any mixture of segregated medical wastes and other wastes which contains more than 30 percent **medical waste** discards is considered to be acceptable as municipal solid waste.

The *Code of Federal Regulations* (CFR) specifically defines a Municipal Waste Combustor (MWC) unit as any device that combusts solid, liquid or gasified municipal solid waste including but not limited to field-erected incinerators (with or without heat recovery), modular incinerators (starved air or excess air), boilers (steam generating units), furnaces (whether suspension-fired, grate-fired, mass-fired or fluidized bed-fired), and gasification/combustion units. This does not include combustion units, engines or other devices that combust landfill gases collected by landfill gas collection systems.

According to the CFR, terms connected with a MWC must be clearly defined. MWC **acid** gases are defined as all acid gases emitted in the exhaust gases from MWC units including **sulfur dioxide** and **hydrogen** chloride gases. MWC organics are defined as organic compounds emitted in the exhaust gases from MWC units including total tetra- (4) through octa- (8) chlorinated di-benzo-p-dioxins and dibenzofurans. This class of chlorinated **chemicals** (where **chlorine** gas binds with certain organic matter, especially **carbon** atoms) includes **dioxin** or TCDD.

EPA also identifies some of following as potential discharges from a MWC: hydrogen chloride, sulfur dioxide, refuse-derived fuel (RDF), **nitrogen oxides**, and **carbon monoxide**. The amounts of these emissions discharged are closely monitored. EPA sets allowable standards and compliance schedules for each **emission**. These standards are legally enforceable regulations.

EPA also sets standards for facility operations. These standards include guidelines for monitoring, for handling ash, for reporting and recordkeeping, for operating the MWC unit within acceptable standards, for maintaining proper combustion air supply levels, and for start-up, shutdown and malfunction of the unit. Compliance and performance testing guidelines are also included in the CFR. These standards and guidelines apply to MWCs constructed, modified, or reconstructed after December 20, 1989. The Code pertaining to MWC is updated periodically. The latest update was issued in February 1991.

However, there are many older MWC units that still burn municipal wastes. These are not as technologically sophisticated or as rigorously monitored as are the newer incinerators. Emissions tests are not as stringent or comprehensive for these older units. They are listed as Sub Part E under the 1971 Code (amended in 1974). These MWC units were constructed, modified, or reconstructed before December 20, 1989, and burn up to 50 tons per day. *See also* Fly ash; Hazardous waste; Scrubbers; Solid waste; Solid waste incineration

Mass extinction

Periodically, every fifty to one hundred million years or so, the earth has experienced mass extinctions, the relatively rapid, large-scale disappearance of many if not most living creatures. The world may be experiencing this phenomenon now at a far more rapid pace than ever before.

Of the five largest mass extinctions, the oldest occurred during the lower Ordovician period some 435 million years ago, when approximately one-quarter of all ocean families, and half of ocean genera, disappeared. (Creatures living in the sea are often used to measure the severity of mass extinctions, because the fossil record of marine sediments is more complete than that for terrestrial animals.) Among the creatures lost during this time were many types of trilobites, cephalopods, and crinoids, all of which are thought to have died out in shallow tropical waters because of sudden changes in ocean levels.

During the late Devonian period, about 357 million years ago, over a fifth of marine families and more than half of marine genera gradually died out over what may have been a ten-million-year interval. **Climate** and sea-level changes apparently doomed many types of corals, trilobites, fish, and brachiopods.

The most severe mass **extinction** of all took place at the end of the Permian period 250 million years ago. This destroyed as much as 96% of all plant and animal **species**, probably over an interval of at least a million years. Over half of all ocean families were wiped out, as were up to 80% of the marine genera. This was fatal for the remaining trilobites and most land species. But the "great dying," as the event is called, also created ecological niches for future life forms, including the dinosaurs.

In the Permian extinctions the suspected but unproven cause is a massive and extremely violent volcanic eruption

in Siberia, which catapulted huge quantities of sunlight-blocking dust and **aerosol** droplets into the **atmosphere**. This, in turn, cooled the climate abruptly, expanding the polar icecaps, shrinking the oceans, and causing a new **ice age**. The rapid fluctuations in sea levels decimated the marine creatures of this period. To make matters worse, volcanic explosions could also have turned sulfate minerals into sulfuric **acid** and **sulfur dioxide** gas, which would have produced a ruinous rain of acidic precipitation. Over a 600,000 year period, these eruptions spewed a flood of molten basalt that created rock formations 870 miles (1400 km) in diameter next to **Lake Baikal**, an area called the Siberian Traps.

Another mass extinction occurred about 198 million years ago, during the late Triassic period, when a quarter of marine families and half or more of marine genera disappeared. Cephalopods, **gastropods**, bivalves, brachiopods, and reptiles, were destroyed, as were the conondonts, the fish from which vertebrates may have descended.

The most recent and best known mass extinction occurred a mere 65 million years ago, at the end of the Cretaceous period. It brought about the end of many creatures, including the dinosaurs and ammonites (shellfish). Sixteen percent of marine families and up to 46% of marine genera were lost at this time.

Scientists are still debating the causes of this catastrophic event. It could have coincided with (and may have been caused or accelerated by) a massive volcanic eruption and lava flood in what is now India, where it created a rock formation called the Deccan Traps. Some scientists suggest that a catastrophic climate change and a drastic cooling of the atmosphere made survival impossible for the dinosaurs, since they had no fur, feathers, or hibernating dens to shield them from the cold, nor could they migrate to a warmer climate. Other experts believe that the explosion of a nearby star cooled the atmosphere and emitted deadly radiation for thousands of years. Or perhaps herbivorous dinosaurs starved because they could not adapt to the new types of vegetation that developed. Their extinction would have killed off the carnivorous dinosaurs that preyed on the plant-eaters. Maybe the dinosaurs could not compete for food with the newly-emerging mammals, which ultimately replaced them as the dominant creatures on the planet.

In truth, much is unknown about the causes of the past mass extinctions. A theory with the weight of some evidence behind it raises the possibility that one or more comets or asteroids may have hit the earth, flinging billions of tons of dust and other debris—or ice crystals, if the object impacted in the oceans—into the atmosphere. By blocking out the sunlight for several months, and plunging the earth into darkness, the collision could have lowered temperatures below freezing, killing off the dinosaurs and the plants on which they fed. This hypothesis is based in part on the 1979 discovery, by Dr. Walter Alvarez of the University of California at Berkeley, of the unusual presence of the precious metal iridium in sediments from the time of the dinosaurs' extinction. Iridium, which belongs to the platinum family of elements, is much more plentiful in meteorites than planetary rocks, but it is also frequently found in strata from volcanic eruptions. Other scientists contend that virtually all mass extinctions could have been caused by volcanic eruptions and the huge floods of basalt resulting from such explosions. Evidence supports both theories. University of Chicago paleobiologist Dr. David M. Raup may have put it best when he wrote, "The disturbing reality is that for none of the thousands of well-documented extinctions in the geologic past do we have a solid explanation of why the extinction occurred."

Mass extinctions are not just a phenomenon of ancient geologic history; the last few thousand years have witnessed several such events, albeit on a far smaller geographic scale than those previously discussed. For example, the extinction of the giant animals of North America appears to have coincided with the arrival of humans on the continent, with the changing climate at the end of the last ice age also a possible factor. Crossing the Bering land bridge linking Siberia and Alaska about 12,000 years ago, primitive tribespeople, possibly from Siberia, found a population of large mammals, including giant beavers, **bison**, camels, mammoths, mastodons, and even lions in North America. These prehistoric hunters, moving south from Alaska towards South America, may have wiped out most of these species within 1,000 years.

Fossil remains of these Pleistocene mammals, some with spear points imbedded in them, reveal such creatures as the elephant-like mastodon; the huge-tusked, shaggy red-haired mammoth; a giant beaver weighing over 400 pounds (181 kg); the fabled saber toothed "tiger"; a 7 foot (2.1 m) wide, long-necked camel; 20-foot (6 m) long ground sloths; a bison 7 feet (2.1 m) high at the hump, with a 6 foot (1.8 m) spread between its horns; and huge **wolves**, lions, bears, and horses.

As the twenty-first century approaches, the earth faces another threat of mass extinctions which may occur over a few years or decades, instead of thousands or millions of years. Particularly endangered are those species that are less well known, and in many cases not yet identified by science. Many of these are plants, animals, and invertebrates found in tropical rain forests, which are rapidly being cut and destroyed.

For example, the 1980 *Global 2000 Report* to the President, compiled by the President's **Council on Environmental Quality** and the State Department, with the help of other federal agencies, projected that "...between half a million and two million species—15–20 percent of all species on earth—could be extinguished by the year 2000." And a report issued

by the **World Resources Institute** in 1989 predicted that "between 1990 and 2020, species extinctions caused primarily by tropical **deforestation** may eliminate somewhere between 5 and 15% of the world's species...This would amount to a potential loss of 15,000 to 50,000 species per year, or 50 to 150 species per day." In 1988, Harvard biologist **Edward O. Wilson** put the annual rate of species extinction at up to 17,500.

Many of these lost species may be potential sources of food or medicines, and may perform essential ecological functions critical to sustaining life on the planet. It is impossible to predict precisely what the effects of these modern mass extinctions will be, but the ecological disruptions that will inevitably occur could have drastic consequences for human welfare and survival. *See also* Acid rain; Biodiversity; Endangered species; Food chain/web; Greenhouse effect; Ice age refugia; Radioactivity; Radiocarbon dating; Rare species; Volcano

Mass spectrometry

A technique of **elemental analysis** first developed by Sir Francis Aston in the early twentieth century. In a mass spectrometer, a sample is first vaporized and then converted to positively charged ions. These ions are accelerated to a high speed and then passed through a magnetic field. Since ions of different weight are bent by different amounts in the magnetic field, elements can be identified on the basis of how far they are bent in the field. Mass spectrometry is a very sensitive analytical technique that permits the detection of trace amounts of a substance, such as the amount of **ozone** in a sample of air. *See also* Measurement and sensing

Mass transit

Mass transit systems transport large numbers of people simultaneously in single vehicles. Examples of mass transit systems include buses, ferries, rapid rail, light rail, commuter rail and intercity rail systems. Although popular before the age of the **automobile**, mass transit systems have become marginal **transportation** modes in many cities in the United States. Recently however, as the negative impacts of automobile use have become of greater public concern, a renewed interest in encouraging mass transit has emerged. The Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991 explicitly allocated funds toward improving mass transit systems.

Transportation congestion is worsening in the United States. In addition to the opportunity costs of time associated with traffic congestion, there are environmental costs associated with automobile use: **emission** of **greenhouse gases**, **air pollution**, **noise pollution**, and increased suburban sprawl and **land use**. Other social costs include increased **probability** of traffic accidents, increased occurrence of stress-related disorders, and increased social severance. Yet in most cities, people seem to be unwilling to use alternative modes of transportation, such as public transit, carpooling, or bicycling, which might impose lower environmental and time costs on society. Nationally, the automobile occupancy rate during commute hours was 1.1 in 1990. Trends indicate the situation will worsen over time.

The social costs associated with automobile use, including environmental **pollution**, congestion, accidents and public health effects, are known in the economics literature as "externalities." These are costs associated with automobile use that are not borne directly by the individuals making the decisions to use their automobiles. Although everyone experiences the negative effects of air pollution, and all drivers experience the negative effects of congestion, each individual driver only experiences a fraction of the total social cost produced when he or she drives. When a driver makes the decision about whether or not to drive an automobile, the full costs of driving are not taken into account. The result is that too many commuters choose to drive, and the social costs far outweigh the private benefits associated with the existing level of driving.

The solution from an economic standpoint is to force drivers to "internalize the externalities" or bear the full cost of their driving. This can be done through policy tools such as congestion pricing or **gasoline** taxes, both of which discourage driving. An alternative solution to the inefficiency is to encourage more use of mass transit by making mass transit less costly to commuters. Many people believe driving is more safe, comfortable, and convenient than mass transit. In order to compete with automobile use, mass transit must either be less expensive than automobiles or more attractive in amenities.

A commonly-held misconception about mass transit is that it must pay for itself. Mass transit is a public good that benefits all commuters, including those who use mass transit and those driving who enjoy less-congested roads and

less-polluted communities. Because benefits are received by both users and non-users, it makes sense for the public sector to be subsidizing mass transit. In fact, because the external benefits of mass transit are difficult to quantify, it is unclear how much subsidization of mass transit is optimal. More subsidization creates lower transit fares and a more convenient system which encourages more riders; both riders and non-riders benefit from this.

In order to be an effective solution to the transportation problem, mass transit should satisfy several criteria. It should be cost-effective and less polluting per passenger mile than automobile use. Its public benefits should outweigh the public costs of operating the system. Investment in mass transit is only worthwhile if it will cause a significant number of people to switch to transit from using automobiles. National **statistics** show the number of vehicle occupants moving closer to one over time, demonstrating the high value the general public seems to place on driving their cars. Alternative modes such as mass transit must be competitive with automobiles in order to cause a decrease in automobile usage and a subsequent improvement in the **environment**.

Mass transit systems have significant environmental benefits, including substantial reductions in greenhouse gases, energy consumption and traffic congestion, provided enough commuters switch to using it. A fully occupied train can remove 100 cars from the road during rush hour, a bus forty, and a vanpool thirteen. Associated energy savings can be around 40–60%, and cleaner fuels can reduce emissions even further. Mass transit systems in different ways. Park and ride systems for example, are much less environmentally friendly than transit-only options. During the first few miles of an automobile trip, emissions and fuel use are very high, due to the cold start. In a 10-mile trip for example, 90% of emissions are produced in the first few miles. Although they offer fewer environmental benefits than full transit systems, they still decrease traffic congestion and accidents.

Not every city in the United States is suited for mass transit systems. Large cities such as New York City and Washington, D.C. have the density of people and businesses necessary to make the systems viable, and mass transit systems are heavily used. Many cities have grown in a sprawling manner, due mainly to the dominance of the automobile, so that the density of the population makes good mass transit infeasible. On the other hand, if a good mass transit system were in place, one could envision the development of business and residential hubs around the transit system which would eventually increase population density and ridership. An addition to the above-mentioned benefits of mass transit, the revitalization of downtowns, many of which have deteriorated with the growth of the suburbs, might occur as development adapts to improved mass transit systems.

Future technological developments might improve the attractiveness of mass transit relative to automobile use. Intelligent Vehicle Highway Systems (IVHS) refer to the application of advanced technologies, especially communications technologies, to improve the efficiency of the nation's surface transportation system. Potential outcomes of this endeavor include the creation and implementation of "smart cars," "smart transit," and "smart streets."

A great deal of IVHS is devoted to improving the efficiency of automobile transportation. IVHS might offer traffic signal timing and smart car technology which would reduce congestion and traffic accidents. These technologies will make automobile use more convenient and safe than before, encouraging more automobile travel. On the other hand, IVHS offers the possibility of implementing a congestion pricing system where automobile users pay a fee when using certain roads at congested times. This cost would make transit more competitive relative to automobiles during heavy commute hours.

Certain components of IVHS might improve convenience to make mass transit more competitive with automobiles. A component of IVHS is the development of communications systems controlling traffic patterns and flows on streets and highways. These systems can be used in conjunction with HOV (high-occupancy vehicle) lanes to make transit systems more competitive in travel time. Also, computerized fare-collection devices speed transit boarding, a time-consuming aspect of present transit travel. These technologies make transit and ridesharing more convenient and attractive to commuters, increasing transit use relative to individual vehicle use.

IVHS could encourage or discourage mass transit use. For planning purposes, it is important to consider the implications of the different components of IVHS to the future of mass transit systems. The benefits associated with increased mass transit use are generally public as opposed to private. Yet, the individual decision about which transportation mode to use is a private decision. Increasing mass transit use requires the development of attractive, competitive mass transit systems that are a convenient, safe, and comfortable option to automobile travel. Improved mass transit in these ways should pay off in terms of an improved environment and quality of life. *See also* Environmental economics; Externality; Urban sprawl

Material Safety Data Sheets

The use of a Material Safety Data Sheet (MSDS), as mandated by the Occupational Health and Safety Administration (OSHA), is an integral part of hazard communication and "right-to-know" in the work place. An MSDS for a chemical substance is designed to provide both workers and emergency personnel with procedures for handling or working with that substance. An MSDS provides information concerning safe handling procedures, first aid measures, and procedures to be taken when the substance is accidentally spilled or released. MSDSs are provided by the manufacturer and supplier of **chemicals** and should be available to all employees at all times. MSDSs for many substances are available on the Internet. Many MSDSs are complete, accurate, and informative, while others, especially for those chemicals a manufacturer considers to be proprietary, may be missing key pieces of information. An MSDS must contain (written in English) the information described below.

An MSDS contains information on ingredients and their physical and chemical characteristics. Except for trade secrets, the MSDS gives the specific chemical name, chemical formula, and common names for the ingredients that have been determined by OSHA to be hazardous chemicals (i.e., any chemical that is defined as a physical or health hazard). If the substance is a mixture that has been tested as a whole to determine its hazardous properties, the chemical and common names of the ingredients that contribute to those known hazards and the common names for the mixture are listed.

If the substance is a mixture that has not been tested as a whole, the chemical and common names are listed for all ingredients that are determined to be health hazards and that comprise 1% or more of the mixture; identified as carcinogens and present at 0.1% or more; or determined to present a physical hazard when present in the mixture.

The MSDS also gives information about physical and chemical characteristics that indicate what a material or mixture is like and how it behaves, including boiling point, vapor pressure, vapor density, water solubility, specific gravity, evaporation rate, and reactivity with water and other substances.

An MSDS also contains information describing hazards, precautions, control measures, and emergency procedures. It describes physical hazards such as combustibility, flammability, and explosiveness, and it identifies health hazards, which include acute and chronic hazards that result from exposure, as well as whether the substance is listed as a confirmed or potential **carcinogen**. In addition, the MSDS gives the applicable precautions for safe handling and use, including steps to be followed if material is spilled or released; waste disposal methods for spilled substances, which must follow federal, state, and local regulations; precautions to be taken in handling and storage; personal protective equipment that are required; signs and symptoms of exposure; and description of routes of entry into the human body during normal usage or a foreseeable emergency. The MSDS describes the applicable control measures such as special fire fighting procedures and extinguishing media and emergency first aid procedures.

Finally, MSDSs describe exposure limits and give information about responsible parties. The document lists the OSHA Permissible Exposure Limit (PEL), the American Conference of Governmental Industrial Hygienists (ACGIH) Threshold Limit Value (TLV), and any other recommended exposure limits that might apply. The MSDS includes the date of preparation or latest revision, with the name of the person responsible for preparing the MSDS being optional. It also lists the name, address, and telephone number of the manufacturer, importer or other responsible party.

[*Judith L. Sims*]

Materials balance approach

A materials (or mass) balance approach for contaminants of public health and/or environmental concern is used to determine the presence, fate and transport of contaminants in the **environment**. The materials balance approach, a fundamental principle of science, engineering, and industrial research and **risk analysis**, is familiar to professionals trained in the physical or life sciences and engineering. The use of a materials balance approach provides a technique to describe the environment as it is today and as it might be under conditions resulting from remedial actions or from changes in the way society produces, uses, and disposes of **chemicals** of environmental concern. It also provides a rational and fundamental basis for asking specific questions and for obtaining specific information, which is necessary for determining fate and transport of contaminants, selecting and evaluating remedial treatment options, and monitoring treatment effectiveness.

The determination or construction of a materials balance is dependent on **conservation** of materials. Material is not created nor is it destroyed by ordinary processes, but it is transformed. When applied to chemicals of environmental concern, conservation of materials requires that a chemical entering a specific environment must be transformed, held in, or transported out of the environment. The amount of a chemical that leaves any process, environmental compart-

ment, or area must be exactly balanced by the amount that enters minus net accumulation within the process or compartment boundaries. This materials balance can be stated as a simple equation:

Change in mass in a volume = Mass entering a volume - Mass leaving a volume

The control volume (compartment) for analysis, the shape of the volume, and the identification of input and output flows as well as the processes acting within the control volume all must be chosen carefully in order for the materials balance to provide useful information for the assessment of environmental impacts and the control of environmental effects.

The steps involved in determining a materials balance of contamination in an environment include:

- Where is the contamination, in what form(s) does it exist and in what concentrations is it present?
- Where is the contamination going under the influence of natural geochemical and geobiological processes (that is, what are key pathways of transport and fate; what are the processes that affect mobility and degradation of contaminants)?
- Based on the answers to questions 1 and 2, how can the contamination be contained, destroyed, or immobilized in the specific phases in which it is found? Through time, as natural and remedial processes act upon specific contaminants, additional determination of the materials balance is required to assess the fate and transport of the contaminants or their transformation products and to develop further treatment or containment methodologies.
- Based on the answers to questions 1 and 2, what environmental phases should be monitored through time to assess the fate and transport of the contamination and effectiveness of treatment or containment under both natural and remedial processes?

Data to answer questions 1 and 2 may be obtained from three categories:

- direct data from administrative records regarding the type and quantity of contamination, as well as where it entered the environment;
- direct data from chemical measurements;
- indirect data from modelling and simulations of natural processes.

Types of direct data may include an assessment of the presence of contaminants in all environmental compartments present in a specific environment, which may include the air phase, aqueous and non-aqueous liquid phases, and solid phases. Contaminants may be transformed partially or completely in the **respiration** process to obtain energy to synthesize new microbial cells, so an estimate of mineralization (for example, by measuring oxygen utilization or **carbon dioxide** production in **aerobic systems**) may also provide important information.

A determination of the **accuracy** of a materials balance assessment is indicated by a good agreement between direct and indirect measurements, suggesting that the control volume was well-bounded and the processes acting within the volume were well-defined. The study of the materials balance approach involves both art and science, but if well-implemented, can provide an understanding of the environment of concern. *See also* Biogeochemical cycles; Risk assessment; Waste management

Ian Lennox McHarg (1920 – 2001)

Scottish design ecologist and writer

Clydebank, Scotland, where Ian McHarg was born and raised (and where he received education through high school) produced one of America's best known design ecologists. Before his first move to the United States, McHarg had attended two colleges in Scotland and spent eight years in the British army, including active battle service in World War II. He entered the army as an enlisted man, after four years attended Officer Training School, and was demobilized in 1946 at the rank of major.

That same year, McHarg entered Harvard University to study landscape architecture, from which he graduated with a bachelor's degree in landscape architecture 1949 and a masters in the same subject, one year later. He returned to Scotland for a short while and then earned another Harvard degree, a master's, in city planning (1951). For a short time,

he returned to Scotland, serving as a planning officer in the country's Department of Health and teaching a course in landscape architecture at Edinburgh College of Art and then at Glasgow College of Art. His career in the United States began in 1954 when he accepted an appointment as an assistant professor of landscape architecture and city planning at the University of Pennsylvania, where a year later he was instrumental in creating the Department of Landscape Architecture.

While many practitioners still consider landscape architecture a traditional design field that creates back yards for the well-to-do, McHarg is widely credited with a revolution in the field. At the university, he taught landscape architecture and planning from an interdisciplinary, ecological perspective, bringing in ecologists, geologists, anthropologists, and even lawyers to participate in team-taught courses. From the university, his students have emerged to foment McHarg's ecological revolution in university design and planning departments, in planning agencies, and in design firms across the country.

As an active designer and planner outside the university McHarg put his ecological ideas into practice in such places as Hazleton, Pennsylvania, Medford, New Jersey, Amelia Island, Florida, Teheran, Iran, and Taroko, Taiwan. What one person can plan and build in a lifetime is limited, so it is McHarg's ideas (and the students, readers, and practitioners instilled with those ideas) that will remain significant far into the future.

The best known distillation and presentation of those ideas is in his *Design With Nature*, published in 1969 and reissued in a twenty-fifth anniversary edition in 1992. Lewis Mumford, in his preface to the first edition, best describes McHarg's accomplishment:

"McHarg's emphasis is not on either design or nature by itself, but upon the preposition *with*, which implies human cooperation and biological partnership. He seeks, not arbitrarily to impose design, but to use to the fullest the potentialities—and with them, necessarily, the restrictive conditions—that nature offers. So, too, in embracing nature, he knows that man's own mind, which is part of nature, has something precious to add that is not to be found at such a high point of development in raw nature untouched by man." Later, Mumford exclaims "here are the foundations for a civilization."

In *Design With Nature*, McHarg tried, and to a large degree succeeded, to direct planning away from its socioeconomic preoccupation toward an in-depth consideration of **environment**; to help integrate the physical and life sciences into an applied **environmental science**; to explore the role of values in planning, and to present a theory and method of planning as a way to understand and channel human adaptations to the environment.

McHarg's ideas changed both landscape architecture and planning, but perhaps the latter more so. In planning, the human ecological philosophy he developed and advocated—in *Design With Nature* (and in numerous articles)—and the very practical method of comprehensive data collection and utilization he worked out in many years of classes and design projects, are today employed worldwide, including integrated applications in new GIS systems. Known by many as the father of ecological planning, McHarg moved from a limited environmental determinism to a contemporary interdisciplinary approach that defines planning as interactive, as applied **human ecology**.

Bill Ernest McKibben (1960 –)

American environmentalist and writer

William E. "Bill" McKibben is an American **nature** writer who was born in Palo Alto, California. He graduated from Harvard University in 1982 and was a staff writer and editor at *The New Yorker* until 1987 when he began his freelance career. He now lives with his wife in the **Adirondack Mountains** in New York, and this region figures prominently in his writings.

In *The End of Nature*, McKibben's first book, he argues that the **greenhouse effect** is not only part of humanity's destruction of the **environment**, but a symptom of Man's alienation from the natural world. He calls for an end to practices that contribute to the greenhouse effect, such as burning **fossil fuels**. Such practices, he writes, "will lead us, if not straight to hell, then straight to a place with a similar temperature."

Some critics dismiss McKibben's arguments as "too absolute," and "more a slogan and hyperbole than scientific insight." Environmentalists, however, praise the book, call-

ing it the "*Silent Spring* of the '90s"—a reference to the book by Rachel Carson which in 1962 awakened the nation to the indiscriminate use of pesticides. However, McKibben's lament over the "end of nature" is a personal account of how human activity has changed not just the industrialized centers of the world, but his own backyard.

McKibbon's second book, *The Age of Missing Information* (1993), is a study of the seduction of television. On one day he videotaped every show on every cable channel available in his area, more than 1,000 hours of television, and then watched it all. To contrast that experience, he spent a day camping in the woods near his Adirondack home. "This book is about the results of that experiment—about the information that each day imparted," he says. Talking about this book, McKibben says, "Television...is a very private experience, with an almost constant message of 'you are the most important, this Bud's for you.' And if you are at the center of the world, it's hard to live environmentally aware."

McKibben has also edited *Birch Browsings: A John Burroughs Reader* (1992). **John Burroughs**, a nature writer whose career spanned 60 years beginning in 1865, is credited with establishing the nature essay as a literary genre. Many environmentalists are returning to the writings of such early nature writers as Burroughs, **John Muir**, and **Aldo Leopold** to study their ideas about **land stewardship**.

Measurement and sensing

A fundamental premise of all scientific research is that scientists can make measurements, expressed in precise mathematical terms, of conditions and events. Indeed, some argue that a field of study can only be called a science to the extent that the data being collected can be mathematically measured. These criteria apply to **environmental science** as they do to other physical and biological sciences.

Measurements serve a number of functions in environmental studies. One is to provide baseline information about certain aspects of the **environment**. A source of concern to scientists and non-scientists alike is the change that appears to be taking place in the earth's **ozone** layer. Mounting evidence appears to suggest that, as a result of human activities, the concentration of ozone in the **stratosphere** seems to be decreasing. That finding is significant because the ozone layer acts as a shield against potentially harmful **ultraviolet radiation** from the sun.

But how do scientists know that changes are taking place in the ozone layer? Such a conclusion can be drawn only if information exists regarding the "normal" concentrations of ozone in the stratosphere. One purpose of measurements, therefore, is to accumulate a huge volume of information regarding the "normal" condition of the environment.

A second purpose of measuring is to determine how some aspect of the environment may be changing, often as a result of human activities. Our concern about the ozone layer, for example, arises out of readings taken by high-flying aircraft over a period of more than a decade. Those readings show consistent changes (decreases) from the level that is regarded as natural or normal. These levels are not fluctuating, that is, decreasing and regaining normalcy. Rather, there is a trend toward decreased ozone levels.

Dozens of techniques are available for measuring environmental characteristics. Many of these techniques are not unique to environmental science. For example, the use of thermometers to record temperatures is vitally important in many environmental studies. But temperature-taking is not a specialized procedure used by environmental scientists. The measurement of **radioactivity** is another example. Geiger counters are used to determine the level of radiation in environmental studies just as they are in scientific research, medical applications, industrial processes and other situations.

Over the years, a number of techniques have been developed for measuring specific environmental characteristics. Many of these techniques can be classified according to their use in the measurement of **air quality** or **water quality**.

An example of the former is the high-volume sampler (HVS) used in measuring particulates in the **atmosphere**.

An HVS is essentially a modified vacuum cleaner that sucks air into a hose and forces it through a filter paper. The difference in the weight of the paper before and after it has trapped the **particulate** matter is used to determine the weight of the particulates. Since the total volume of air passing through the HVS can be easily measured, the systems provides of measure of particulates in mass per volume.

Techniques for measuring various components of a gas are also becoming more sophisticated. At one time, for example, the determination of ozone levels was made simply by suspending a piece of natural **rubber** of known size and weight in the air. Since ozone causes rubber to crack, the speed at which cracking occurred was taken as a measure of ozone levels in the air.

As with most other gases, ozone is now measured by chemical means. A sample of gas is passed through some device, often a "bubbler," that contains a compound that will react with the gas being tested. The concentration of that gas can be measured, then, by determining the amount of chemical change that takes place in the measuring device.

For example, a reaction with which many high school students are familiar can be used to determine the level of **sulfur dioxide** in the air. Sulfur dioxide reacts with **lead** dioxide (PbO_2) to form a characteristic black precipitate of lead sulfate.

$$SO_2 + PbO_2 \rightarrow PbSO_4$$

If lead dioxide is added to a bubbler through which a sample of gas is passed, the amount of darkening in the device (due to the formation of lead sulfate) is a measure of the concentration of sulfur dioxide in the gas.

Many environmental measurements now make use of sophisticated chemical techniques. One example is infrared spectrometry. The term *spectrometry* refers to the measurement of energy absorbed or emitted by various compounds. All molecules are held together by electrons that vibrate with characteristic frequencies. If energy is added to those molecules, they will absorb frequencies of energy that match their characteristic frequencies, but no others. Each kind of molecule can be identified, therefore, by a "map" of the frequencies that it does and does not absorb.

Infrared spectrometry is the most common form of the technique used because most molecules vibrate with frequencies in the infrared region. Techniques such as infrared spectrometry are valuable because they can detect concentrations of a material at much lower levels than can most chemical systems.

The increasing sophistication of measuring techniques does not mean that all simple procedures have been abandoned. For example, one method for measuring the level of **air pollution** requires no more than good eyesight and a reference card. The reference card contains the Ringelmann scale, a set of six squares that range from pure white to pure black. Each square contains an amount of hatching that corresponds to completely pure air (pure white, no hatching) to badly polluted air (totally black). The four intermediary squares contain increasingly more hatching, constituting equivalents of 20 percent, 40 percent, 60 percent and 80 percent "blackness."

For comparison, opacity (darkening) of air can also be determined by electronic means more precisely. A photometer, for example, is a device that records the amount of light transmitted by a sample of air. The light is converted to an electric current that can be read on a meter. In some industrial and **power plants**, a photometer is attached to the smokestack to obtain a continuous record of the opacity of the gases being emitted.

The two most common types of air quality measurements are those for **ambient air** quality and emissions. Ambient air refers to the outdoor air that surrounds us. Ambient air quality measurements provide information on the possible accumulation of harmful compounds such as **carbon monoxide**, sulfur dioxide, **nitrogen oxides**, and **hydrocarbons**.

Emission measurements reveal the level of such compounds being released from a power plant, a factory, or some other source. In many cases, emissions can be studied by simply drilling a hole in a smokestack, extracting a small sample of exhaust gases, and studying their composition by methods described above.

Many biological, chemical, and physical methods are available for measuring water quality. The presence of pathogens in a sample of water can be determined, for example, by standard bacteriological techniques in which a water sample is allowed to incubate for some period of time and the number of bacteria produced counted visually or electronically.

At one time, most water tests were fairly straightforward chemical tests. The concentration of **nitrogen** in a water sample, for example, can be determined by a standard procedure known as the Kjeldahl test and the amount of **chlorination** by precipitation with a silver salt. Today, most water tests can be conducted by more sophisticated instrumental techniques. A photometer can be used to compare an unknown water sample with a known standard to determine the concentration of nitrogen, **phosphorus**, **chlorine**, or some other component.

One of the most basic measurements of water quality is that of oxygen demand. The more polluted a water sample is, the more organic matter it is likely to contain. The more organic matter, the greater the amount of oxygen the sample will require to decompose the organic material.

Traditionally, the method for determining this characteristic was **biochemical oxygen demand** (BOD), a test in which a sample of water is studied over a five-day period. To overcome the lengthy time required to conduct this test, modifications such as total organic **carbon** (TOC) have been developed.

Specialized measuring techniques are sometimes required for particular types of environmental studies. Determining the amount of **noise pollution** in an area, for example, requires the use of a sound level meter, a device consisting of a microphone, amplifier, frequency-measuring circuit, and read-out screen.

One consequence of the improved technology now available for making measurements is that smaller and smaller concentrations of a substance can be detected. Chemical means can routinely detect the presence of a substance to the level of one part in a thousand or one part per million (ppm). The most advanced technologies today have stretched that sensitivity to levels of one part per billion (ppb) and even one part per trillion (ppt).

The efficiency of these measuring devices poses some new issues for environmentalists. What does it mean, for example, to learn that a **toxic substance** exists in the **soil** at a level of one ppb if we know the material is harmful only in much higher concentrations? Does any level of exposure to the substance pose a hazard, or can we safely ignore such a minuscule quantity of the substance?

A field of measurement of increasing importance in environmental studies is remote sensing. The term refers to any method by which an object or an area is studied at some great distance. Most commonly today, the term is used to describe surveys of the earth's surface by satellites orbiting around it.

Remote sensing procedures depend on the fact that various types of materials absorb and reflect **solar energy** in different ways. Instruments in satellites that can measure these differences can, therefore, detect variations in land and ocean surfaces.

Remote sensing uses three parts of the electromagnetic spectrum: the visible, infrared, and microwave regions. Perhaps the most common form of remote sensing is that which uses photography. Photographic equipment has now been developed to the point where objects of no more than a few yards apart can be distinguished from outer space.

Since some objects and features emit radiation in electromagnetic regions other than the visual, infrared, and microwave techniques are also used. The images obtained from any one of these methods can be further improved by computer enhancement of the original photographs.

Remote sensing has now been used for a number of environmental applications. Some examples include the locating of possible mineral reserves, the tracing of water **drainage** patterns, the determination of soil moisture, the tracing of plant diseases, the calculation of snow and ice masses, and the measurement of biological productivity in the oceans. *See also* Drinking-water supply; Emission standards; Greenhouse gases; National Ambient Air Quality Standards; Ozone layer depletion; Radiocarbon dating; Water pollution

Medical waste

Medical waste is a subcategory of **hazardous waste** that is attracting increasing concern. The **Environmental Protection Agency** (EPA) lists the following categories of medical waste: cultures and stocks; pathological wastes which includes body parts; blood and blood products; used "sharps" such as needles and scalpels; **animal waste** or animal corpses which have been inoculated with infectious substances in medical research; isolation wastes, which come from people with highly contagious diseases; and unused, discarded "sharps."

Ten to fifteen percent of medical waste is considered infectious, although guidelines on just what is infectious medical waste vary from state to state. As a result, state and federal guidelines on disposal of these wastes are a hodgepodge of confusing laws and regulations. And the guidelines that do exist usually exempt generators of 50 pounds (23 kg) or less per month from any regulatory action.

The need to address medical waste began soon after such items as syringes, IV bags, and scalpels were observed washing up on ocean beaches in the summer of 1988. Congress directed the EPA to gather data on their sources, associated health hazards, and current procedures and regulations for management and disposal and to evaluate the health hazards associated with transporting them, incinerating them, burying them in a **landfill**, and disposing of them in a sanitary sewer system.

A two-year, voluntary program enacted by Congress, the Medical Waste Tracking Act of 1988, was instituted in response to public concern over the treatment of medical waste. The Act created a "cradle-to-grave" tracking system based on detailed shipping records, similar to the program in place for hazardous waste. The pilot program has now

expired, the EPA data has been sent to Washington administrators, and any action on the findings of the EPA's study is in limbo. It is doubtful that the EPA report on medical waste will ever be submitted to Congress or find its way into the *Federal Register* because many of the states that participated in the program went on to pass strict medical-waste management guidelines of their own. All the states participating at least revised their **municipal solid waste** guidelines to include the category of medical waste, whether or not management practices were included.

Another complicating factor in the regulation of medical waste is that at least four different federal agencies are involved with medical-waste issues: the EPA, the **Occupational Safety and Health Administration** (OSHA), the Centers for Disease Control (CDC), and the **Agency for Toxic Substances and Disease Registry**.

The EPA's study reported that 3.2 million tons of medical waste was produced in the United States each year. Not surprisingly, hospitals, long-term health care facilities, and physician's offices are the major producers of medical wastes, which account for about 0.3% by weight of all municipal **solid waste**. The EPA found out that current practices of management and disposal range from handling the waste as nonhazardous municipal solid waste to strict segregation, packaging, labeling, and tracking from the generator to the disposal site, the so-called "cradle-to-grave" management.

Health care workers are required by federal law to segregate medical waste in special containers; if the waste is transported for treatment, it must be labeled with the generator's name and carry a biological hazard symbol. But facilities that produce less than 50 lb (23 kg) of medical waste per month are exempt from most requirements. Home and small generator medical wastes fall through the cracks. Insulin-dependent diabetics, for instance, typically dispose of used syringes in their household trash or flush them down the toilet. In some northeastern cities, New York City for example, antiquated sewage systems pour material into rivers and oceans during heavy rainfalls. Depending on tides and currents, syringes can end up on beaches, which is what New York and New Jersey coastlines experienced in 1988 and 1989.

A growing source of medical waste that is not regulated is that generated by home health-care providers. As a result of new patient-care strategies and rising medical costs, more long-term illnesses are being treated at home. That means that medical waste is being disposed of in ordinary household trash. Medical clinics and intravenous drug users are also suspected of contributing to unsafe dumping of medical wastes. Even U.S. Navy vessels contributed to beach medical waste.

The need to address the problem evolved long before wastes washed up on northeastern beaches, however. Over the last 10 years, and partly in response to the **AIDS** and hepatitis epidemics, the use of disposable health care products has contributed to the increased volume of medical waste. Cost-containment measures have increased the use of plastic disposables in health care settings. From syringes to bedpans, health care aids are increasingly thrown away.

Common treatment techniques of medical waste include steam sterilization and **incineration**, although some waste is discarded into sewage systems. During autoclaving, the waste is exposed to steam at a temperature of 250°F (121°C) for at least 45 minutes. Autoclaving fails to reduce the volume of waste that must be landfilled, and is only preferred in areas where there is no appropriate incineration equipment. Proper incineration efficiently destroys all categories of infectious wastes, effectively kills live and dormant forms of pathogenic organisms, and alters the waste volume.

About 60 percent of medical waste is treated on site at hospital facilities. After treatment, ash residues or sterilized and disinfected materials must be transported to commercial treatment facilities or taken directly to landfills. Other options for medical waste treatment include **compaction**, microwaving, and mechanical or chemical disinfection, which could be less costly and alleviate concerns about emissions from incinerators.

According to the congressional Office of Technology Assessment (OTA), air emissions of **dioxin** and **heavy metals** from hospital incinerators average 10 to 100 times more per gram of waste burned than emissions from well-controlled municipal waste incinerators. And while waste generators are generally required to track with manifests the route their wastes take to reach disposal, strict requirements do not exist for on-site treatment facilities.

Some industry watchers, environmentalists, and policy makers are advocating a medical waste disposal program similar to some in Europe. Virtually all medical wastes in Switzerland and Germany, for example, go to regional incineration facilities. Stringent air-quality regulations in these countries make it impractical for hospitals to do on-site incineration, but the regional facilities made advanced **air pollution control** devices cost-effective. In Munich, operators dump the resulting ash in specially lined landfills. Hospitals in Canada are turning away from disposable supplies in favor of products that can be cleaned and reused.

For a regional system to work, however, medical waste must be safely transported. In the United States, there are no federal statutes governing the transport of medical refuse. Refrigerated trucks legally can and do carry food after transporting medical wastes.

A proposal to manage home users of syringes and medicines that end up in municipal solid waste landfills would include a pharmacy "swap" system. In Switzerland and Germany, for example, pharmacies accept old medicines

for appropriate disposal, then send the medicine to regional incineration outlets. A deposit-and-return system on syringes has been advocated in this country to insure the safe disposal of syringes.

Mediterranean fruit fly

The Mediterranean fruit fly (referred to as Med fly, or Moscamed in Spanish), *Ceratitis capitata*, is one of the most destructive fruit pests in the world. The United State has suffered infestations of Med fly in California, Texas, and Florida, but with aggressive detection and eradication programs, the Med fly has not yet become established in the United States. However, eradication efforts are difficult and expensive. There is a loss of crop yield associated with the infestation, control measures are costly, and both fresh and processed fruit and vegetables must be sorted. Some countries maintain quarantines against the Med fly, which eliminates potential markets when Med fly becomes established in an area.

The Med fly, which originated in Africa, is widely distributed throughout the world, as it has a wide range of hosts and is able to tolerate colder climates better than most other **species** of fruit flies. It has caused infestations in over 85 countries in tropical and subtropical regions. Since 1929, the United States has been involved in several outbreak and eradication programs. The Med fly became established in Hawaii in 1910. Hawaii remains infested, and there is no eradication program currently under way.

Med fly larvae can develop and feed on most deciduous, subtropical, and tropical fruits and some vegetables. It has been shown to attack more than 260 different fruits, flowers, vegetables, and nuts. The Med fly prefers thin-skinned, ripe succulent fruits such as deciduous fruits (for example, pear, peach, and apple) more than citrus fruits. The larvae feed on the pulp of fruits, tunneling through it, and reducing the fruit to an inedible juicy mass. In the Mediterranean countries, often only the earlier maturing fruits are grown, because later maturing fruits would be too heavily infested to be marketable. Harvesting before complete maturity is also practiced in Mediterranean areas with Med fly infestations.

The adult Med fly is slightly smaller than a common housefly. It is colorful, with dark blue eyes, shiny black thorax (back), and a yellowish abdomen with silvery cross bands. Its droopy wings are covered with yellow, brown, and black blotchy spots and bands.

The life cycle of the Med fly has fives phases: (1) the adult female pierces the skin of a fruit or vegetable with a needle-like ovipositor and deposits one to 10 eggs (other Med flies may deposit in the same puncture); (2) eggs hatch into maggots (worm-like, legless larvae); (3) larvae feed upon the pulp of the fruit or vegetable before dropping to the ground; (4) the larvae transform into pupae into the **soil**; and (5) the pupae mature into adults and emerge from the soil. The life cycle is completed in 21–30 days under tropical summer weather conditions.

An eradication program consists of three areas of action: survey, regulation, and control.

The Animal and Plant Health Inspection Service (APHIS) of the **U.S. Department of Agriculture** in cooperation with state departments of agriculture survey high-risk areas of states susceptible to Med fly infestations by conducting **trapping** programs. If one or more Med flies is collected in a trap, APHIS and state officials implement a survey to determine if there is an infestation and if so, to define the limits of the infested area. Using the original detection site as the focal point, additional traps are placed and monitored.

If an infestation is identified, then federal and state regulations dictate that a quarantine must be imposed to prevent the spread of the Med fly. Federal quarantine laws prevent the interstate movement of any article that might harbor the fly. State regulations control the movement of these articles going to uninfested areas within the same state. The regulated articles include all of the fruits and vegetables within the area that could serve as a Med fly host. Open-air vegetable and fruit stands are required to cover produce to prevent infestation. All commercial and home-grown produce may not be transported without inspection and treatment.

To eradicate a Med fly infestation, three kinds of treatment are used alone or in combination. An aerial and ground bait spray can be used that contains a protein/sugar bait to attract the fly and an insecticide in minimal amounts to kill the flies.

In the Sterile Insect Technique (SIT), Med flies are raised in large numbers, sterilized with a non-lethal dose of irradiation, and released into infested areas, where they mate with the wild Med flies. As these matings do not produce offspring, the wild population is eliminated through attrition. This technique is most effective in areas with low Med fly populations where a high proportion of sterile to wild Med flies can be achieved. Before the use of SIT, bait spray can be applied to decrease local populations down to lower densities.

The third method is to apply insecticide to the soil under host trees, where the insecticide kills some larvae as the enter the soil to pupate but most of the adults as they emerge from the ground. Application of insecticide to the soil is used only when larvae are detected. The preferred method of eradication control is an integrated approach, using all three treatments, with the use of SIT emphasized.

To prevent Med flies from being brought into the United States, APHIS administers agricultural quarantine laws to keep foreign plant pests and diseases from being brought into the country. Travelers coming to the continental United States from Hawaii or a foreign country are not allowed to bring into the country fresh fruits, meats, plants, birds, and plant and animal products. In fiscal year 1998, when 400,000 aircraft were cleared to bring travelers and cargo into the United States, APHIS officers intercepted more than 1.8 million illegal plants, animals, or plant and animal byproducts. More than 52,000 plant pests and diseases known to be dangerous to the U.S. agricultural industry were also intercepted.

If Med fly were to become established in the United States, prices of fruits and vegetables would increase, and produce would become less available. Both commercial production areas and backyard gardens would require the application of more pesticides on a regular basis. In 1993, APHIS estimated that annual losses due to Med fly infestations would be about $1.5 billion annually, if Med fly were to become established in the United States. These losses would be due to export sanctions, lost markets, treatment costs, reduced crop yields, and premature fruit drop.

[*Judith L. Sims*]

Mediterranean Sea

For centuries, the Mediterranean Sea has been the focal point of western civilization. It is an area rich in history and has played critical roles in the development of shipping and trade, as a resource for feeding growing populations, and as an aid to the spread and mingling of races and cultures.

The Mediterranean began to form about 250 million years ago when the Eurasian and African continental plates began moving toward each other, pinching off the Tethys Sea, an extensive shallow sea that separated Europe and much of Asia from Africa and India. It now has only two outlets, the Straits of Gibraltar and the Bosporus, a narrow strait between the Mediterranean and Black Seas. While the central basin of the Mediterranean reaches depths of several thousand yards, there is a sill under the Straits of Gibraltar that is only 1,970 feet (600 m) below the surface. Through this passageway flows surface water from the Atlantic Ocean.

Since the Mediterranean is situated in one of the world's **arid** belts, the inputs from precipitation and rivers is far less than the water lost through evaporation. If the straight at Gibraltar were to close due to further plate movements, the Mediterranean would dry up. In fact, data from the Deep Sea Drilling Project, seismic surveys, and fossil analysis have found evidence of salt deposits, ancient river valleys, and fresh water animals, all suggesting that this has occurred at least once. Since the African and Eurasian plates are moving together, this will probably happen again.

Humans can do nothing about this impending geological disaster. There are, however, events that people can influence. Domestic sewage, industrial **discharge**, agricultural **runoff**, and **oil spills** are seriously threatening the Mediterranean, fouling its once clear waters, altering its chemical cycling, and killing its organisms. Along its northern coastline are some of the most heavily industrialized nations in the world, whose industries are destroying nearshore nursery habitats, damaging fisheries. **Dams** on inflowing rivers reduce the **sediment** inputs, making coastal **erosion** a major problem. Shipping, once the hallmark of Mediterranean civilization, releases every manner of waste into the Sea, including oil. Annually, 6 million barrels of oil end up in the Mediterranean. The limited water circulation patterns of the Mediterranean compound this problem as pollutants accumulate.

Today seafood contamination and eye, skin, and intestinal diseases are frequently experienced by coastal residents. Marine mammal and sea turtle populations are threatened by **habitat** loss and nondegradable pollutants dumped into the waters. Sea grass (*Posidonia oceanica*), which provides food and habitat for some 400 **species** of algae and thousands of species of fish and invertebrates, is disappearing. **Nutrient** enrichment of the Mediterranean results in large **plankton** blooms which, combined with destructive fishing practices, contribute to the demise of the sea grass beds.

These problems have been recognized, and efforts are being made to reverse the declining health of the Mediterranean. Early efforts included the 1910 construction of one of the first institutions for study of the seas, the Musée Oceanographique by Prince Albert I of Monaco. Since then, the conflicts between the political and religious ideologies of the 18 nations surrounding the Mediterranean have been

major hurdles in completing cleanup plans. In 1976, the *Mediterranean Action Plan* was signed by 13 of the nations. A major component of this agreement was the Blue Plan, a study of future effects of increasing coastal populations. Other efforts include the Genoa Declaration in 1985 and the Nicosia Charter in 1990. The latter commits resources of the community, the **World Bank**, the European Investment Bank, and the **United Nations Environment Programme** to achieve a Mediterranean **environment** compatible with **sustainable development** by 2025. Hopefully, these efforts can reverse the decline of this natural wonder. *See also* Algal bloom; Biofouling; Commercial fishing; Environmental degradation; Ocean dumping; Water pollution

Megawatt (MW)

A megawatt is a unit of power equivalent to one million watts (10^6 watts), or one thousand kilowatts. As a unit of power, a megawatt expresses the rate at which energy is produced. A megawatt is equivalent to one million joules per second. A megawatt is a fairly large unit of power and is used, therefore, when discussing the size of a power plant, a nation's total energy-generating capacity, or some other such large statistic. For example, the total electrical energy generating capacity for the state of California in 1988 was 45,900 megawatts. *See also* Energy and the environment; Energy efficiency

Chico Mendes (1944 – 1988)

Brazilian union leader, conservationist, and activist

Francisco Alvo Mendes Filho, known as Chico Mendes, was a defender of the tropical rain forests and a champion of the concept of sustainable harvest as a means of saving and protecting that threatened **ecosystem**. As president of the local Rural Workers Union, representing **rubber** tappers in his native Brazil, Mendes became too powerful and politically influential for ranchers who wanted to turn the **rain forest** into grazing land for their cattle. The struggle between them ended in 1988, when Mendes was assassinated.

Chico Mendes. (Corbis-Bettmann. Reproduced by permission.)

Chico Mendes was born in 1944 in Acre Province of Brazil, along the upper reaches of the Amazon River not far from the border with Peru and Bolivia. Following his father, he was a *seringueiro*, a rubber tapper. He farmed a small clearing, but relied on the sale of rubber from several hundred native rubber trees in the rain forest itself to provide income for him and his family. Mendes inherited the land and the trees from his father who had begun tapping them in the 1930s. Two long v-shaped cuts made with care in the bark of each rubber tree would yield one or two cups of the milky latex sap each week, which could then be dried to make natural rubber.

Mendes would also collect other natural forest products, such as fruits and Brazil nuts, to supplement his income. There are approximately 100,000 other rubber tappers living throughout the rain forest, and this is what they do as well. It is sustainable harvest which does not destroy the forest and provides a substantial income. On average, **logging** yields a one-time profit of $1,290 per acre; if the land is converted to cattle pasture, it yields an income of about $61 per acre per year. The sustainable yield of forest products, on the other hand, provides an income of $2,762 per acre per year.

Land speculators and large cattle ranching concerns are more interested in the short-term profits they can realize

by cutting down the forest, selling the timber, and converting the land for cattle grazing. Ranching requires huge tracts of land, and satellite images indicate that in 1988 alone about 30 million acres of forest was destroyed for this industry. Low land prices, low tax rates, and direct subsidies to ranchers further encourage this practice. The Brazilian government had further aided ranching by building and maintaining roads into the forest, which are then used to ship cattle to market.

Chico Mendes fought to end this destruction of the **tropical rain forest**. He made many political inroads, gaining influence with the Interior Ministry as well as the public. His main adversary was Darli Alves da Silva, a cattle rancher who had begun acquiring forest land in Acre through strong-arm tactics and he vowed that Mendes would not live out 1988. Mendes had helped establish several forest reserves that year, thus all but ending forest clearing in Acre.

Mendes, his wife, and two policemen assigned to guard him were playing cards at his home on the night of December 22, 1988. Mendes stepped outside for a moment and was killed by a shotgun blast to the chest from a waiting assassin. The local police claimed no clues or suspects in the case, but local and international protests forced the Brazilian government to enter the investigation. Evidence led them to the ranch of Darli da Silva. In the summer of 1989 indictments for murder were handed down to Darli da Silva, his son Darci Pereia da Silva, and Jerdeir Pereia, one of da Silva's ranch hands. Testimony indicated that Darli ordered the murder and that Darci supervised as Jerdeir carried out the plot. There is evidence that other prominent ranchers may have been involved in the plot, and they are currently under investigation.

Mercury

Mercury is a naturally occurring element in minerals, rocks, **soil**, water, air, plants, and animals. The predominant forms in the **atmosphere**, water, and **aerobic** soils and sediments are elemental and mercuric mercury; while cinnabar is commonly found in mineralized ore deposits and **anaerobic** soils and sediments. Mercury is present throughout the atmosphere because of its relatively high vapor pressure. It vaporizes from the earth's surface and is transported in a global cycle, sometimes for hundreds of kilometers, before being deposited again with particulates, rain, or snow. The background concentrations in rocks and soils typically range between 20 and 100 μg Hg/kg with a worldwide average of about 50 μg Hg/kg. Natural background concentrations in the uncontaminated atmosphere are in the order of between 1 and 10 ng/m^3 increasing to between 50 and 1,000,000 ng/m^3 or more over mineralized areas. Mercury is transported to aquatic ecosystems via surface **runoff** and **atmospheric deposition**. Airborne concentrations associated with **anthropogenic** activities such as **coal** burning, smelting, industry, and **incineration** range between 100 and 100,000 ng/m^3.

The annual worldwide production from cinnabar was about 11,500 metric tons in 1990. The element can be divided into two major categories, organic and inorganic. Inorganic mercury includes the elemental (Hg^0) silvery liquid metal (mp, 38°C; bp, 357°C) as well as mercurous **ion** (Hg^+), mercuric ion (Hg^{++}), and their compounds. Organic mercury includes chemical compounds which contain **carbon** atoms that are covalently bound to a mercury atom, such as methylmercury (CH_3-Hg^+).

During the latter half of the twentieth century, inorganic mercury was used extensively to produce caustic soda and **chlorine** as well as to manufacture batteries, switches, street lamps, and fluorescent lamps. Gold mining, dental amalgams, pharmaceuticals, and other consumer items also consume inorganic mercury. Organic mercury applications have mostly been eliminated in agricultural fungicides, slimicides in paper pulp production, bacteriostats in water based paints, and industrial catalysts.

Over the centuries the symptoms of inorganic mercury **poisoning** were well documented by the exposure of miners and industrial workers as mercury accumulated in their brains, kidneys, and livers. Loose teeth, tremors, and psychopathological symptoms were common at low exposure, but removal from the source would often enable the victims to recover. However, the effects of organic alkyl mercurials, such as methylmercury, were more severe. With a **half-life** in the human body of about seventy days, continued exposure elevates the levels. It also crosses the blood/brain and placental barriers, attacking the central nervous system and inducing teratogenic changes in the fetus. The neurological symptoms include: loss of coordination in walking; slurred speech; constriction of the field of vision; loss of sensation, especially in the fingers, toes, and lips; and loss of hearing. Severe poisoning can cause coma, blindness, and death.

The concentrations of mercury in the ocean and uncontaminated freshwater are generally believed to be less

than 300 and 200 ng/l respectively. However, new ultra clean analytical techniques indicate that the actual concentrations may be three to five fold lower. In contaminated aquatic systems concentrations as high as 5 μg Hg/l have been reported. In the water column, mercury readily adsorbs onto organic particulates, metal oxides, and clays. Then they settle into the sediments. Historically, depending on their location, the natural background concentrations of mercury in sediments have ranged between 10 and 200 μg/kg. However, most aquatic systems have received some mercury contamination, and the rate has increased during the past century. Among sites that have been measured, the total concentrations have usually been from five to ten times greater than background and ranged from less than 0.5 mg Hg/kg (dry weight) in remote areas to 2010 mg Hg/kg (dry weight) in Minamata Bay, Japan.

In the aquatic **ecosystem** inorganic mercury is converted to methylmercury by both biotic and abiotic processes. It is then released, and aquatic organisms bioaccumulate it easily and metabolize and excrete it very poorly. The biological half-life in fish may be as long as one to three years. Exposed organisms at each level of the food chain bioconcentrate methylmercury and pass it on to animals at the higher trophic levels.

Depending on the **species** of fish and the type and amount of mercury being released from the sediments, it may be magnified biologically from 1,000 and 100,000 times or more. While background levels of total mercury in freshwater and marine fishes from unpolluted waters typically range from less than 0.1 to about 0.2 mg Hg/kg, higher concentrations are found in some pelagic top predator ocean fishes such as tuna and shark, sometimes exceeding 1.5 mg/kg. Conversely, fish from contaminated waters typically contain levels between 0.5 and 5.0 mg Hg/kg and up to 35 to 50 mg Hg/kg in highly contaminated areas.

Several standards have been developed to protect the public's health from the threat of mercury poisoning. The **maximum permissible concentration** allowed by the United States **Environmental Protection Agency** (EPA) under its drinking water standards is 2 μg Hg/l. The United States **Food and Drug Administration** guideline for mercury in seafood is 1 mg Hg/kg freshweight; however, some states, such as Michigan, adhere to a more restrictive guideline of 0.5 mg Hg/kg freshweight. The Food and Agriculture Organization of the United Nations (FAO), on the other hand, recommends a provisional tolerable intake (PTI) of 0.3 mg mercury per week for a person weighing 154 lb (70 kg), of which no more than 0.2 should be in the methylated form. *See also* Biological methylation; Birth defects; Food chain/web; Minamata disease; Teratogen; Water pollution; Xenobiotic

Metabolism

The sum total of biochemical reactions occurring in living organisms by which energy is made available to the organism. Metabolism consists of *catabolism*, the chemical breakdown of large molecules into their smaller molecular components (e.g., from proteins to amino acids), and *anabolism*, the reconstruction or chemical synthesis of large molecules. In physiology, metabolism also describes regulated sequences of chemical reactions (physiological pathways), such as protein metabolism or urea metabolism. In **ecology**, the metabolism of lakes or ponds is the sum of the chemical reactions taking place between the inhabitants and the **environment**.

Metals, as contaminants

Metals, objects made from metal, and chemical compounds containing metal are pervasive in the home, workplace, and **environment**. Although metals play an essential role in modern human society, there are many instances where they occur as unneeded and harmful contaminants. **Heavy metals** such as **mercury**, **cadmium**, **lead**, **uranium**, chromium, manganese, **nickel**, thallium, and bismuth are all industrially useful, but they are also potentially harmful at high concentrations in the environment or when found in food or drinking water. Environmental contamination with heavy metals can result from many activities including mining, large-scale **combustion** of **coal** in heating or **power plants**, mineral and metal processing, and use of fungicides and pesticides.

The metal mercury (Hg), a useful component of many products including thermometers, pesticides, drugs, paints, and batteries, is unusual in that it is a liquid at ordinary temperatures. It forms a variety of useful salts and organic compounds. Misuse of products containing mercury can lead to serious health problems. Disorders caused by mercury depend on the form of mercury ingested and the method of exposure. Ingestion of mercury salts can lead to kidney damage and death. Exposure to mercury vapor can lead to inhalation or **absorption** through the skin. Brain function is affected, and loss of memory, depression, anxiety, and other personality changes may result. Ingestion of organic mercury compounds used in pesticides can result in permanent neurological damage. One very serious mercury **pollu-**

tion incident occurred in the 1950s at Minamata Bay, Japan, where releases of mercury in **effluent** from a manufacturing plant were ingested by fish. People eating the fish developed serious, and in some cases fatal, neurological maladies. Infants and children were particularly vulnerable to this "Minimata disease."

Lead (Pb) has been used for many purposes for thousands of years. However, toxicity has been largely unnoticed or ignored until recent decades. Lead uptake by the body is quite slow, but its rate of excretion is even slower. Thus in cases of long term exposure, lead levels in the body gradually increase. There are many sources of contamination. Lead water pipes were once used to carry domestic water. Until recently, lead-containing solder was use to join **copper** piping in homes. Lead contamination of drinking water resulted, and symptoms of lead toxicity were noted in those who used the water. Until recently, white lead pigment was widely used in house paint. Deteriorating and chipping paint poisoned occupants, particularly children, who accidentally ingested or inhaled dust and fragments. Symptoms of lead toxicity can be both chronic and acute. Weakness, loss of appetite, **anemia**, vomiting, and convulsions have all been reported. Lead causes lesions in the central nervous system and serious long-term damage.

Cadmium (Cd) is useful both as an element and in compounds. The element is a lustrous silvery metal that is usually associated in **nature** with zinc. It is used to plate steel, copper, brass, and other alloys and serves to retard corrosion. Cadmium oxide is used in nickel-cadmium storage batteries and as a pigment in paints and inks. Although metallic cadmium is not dangerous under ordinary conditions, cadmium ions, produced when the metal is attacked by mineral acids, are very toxic. Toxicity symptoms resemble those of mercury.

Uranium (U) with an atomic number of 92, is one of the heaviest of all elements. Once thought to be rare, it is now known to be widely distributed in the Earth's crust. Its concentration in sea water exceeds those of mercury and cadmium and is at about the same level as copper and lead. Interest in uranium and its use expanded dramatically with the development of atomic power and **nuclear weapons**. Environmental and health concerns have centered on the radioactive nature of uranium, but chemical toxicity is also a potential problem. Uranium contamination surrounding mining and mill **tailings** in southwestern United States has been a major concern for Native Americans living nearby.

Each of the heavy metals has its own specific toxic effects on human health and the environment. Before this fact was generally realized, mining, smelting and manufacturing activities often resulted in appalling instances of environmental contamination. While greater concern has resulted in improvement, serious problems remain in instances where proper control has not been practiced.

Meteorology

Meteorology is derived from the Greek words *meteora* meaning things in the air or things above, and *logy* meaning science or discourse. It is a branch of physics concerned with the study and theory of atmospheric phenomena and is frequently equated to atmospheric science. One of the earliest references to this branch of physics is Aristotle's *Meteorologica* written around 340 B.C.

In the modern context meteorology is founded upon the basic physical principles and laws governing the energy and mass exchanges within the earth's **atmosphere** and involves the study of short term variations of atmospheric properties (temperature, moisture, wind) and interactions with the earth's surface. The ability to predict and explain short term changes in the atmosphere from observations and numerical models (using the laws of physics) is an important dimension of meteorology as well. Thus the words meteorologist and forecaster are often used interchangeably to describe someone who can predict the weather.

Meteorologists are trained in observations, instrumentation, data processing, and **modeling** techniques for the purpose of analyzing and predicting trajectories of major weather systems, including their associated temperature, precipitation, wind, and sky conditions. Modern methods include the use of automated surface observation systems, radar, satellites, radiosondes, wind profilers, and high resolution computer models (sometimes called global circulation models) to estimate temporal and spatial variability. *See also* Acid rain; Climate; Cloud chemistry; Hydrologic cycle; Photochemical smog

Methane

An organic compound with the chemical formula CH_4, methane occurs naturally in air at a concentration of about 0.0002 percent. It is produced in processes such as the **anaerobic** decay of organic matter, the growth of certain types

of plants, and the belching of cattle. Methane is the major component of **natural gas**, making up about 85 percent of that fuel. Environmental scientists are increasingly concerned about methane as a possible greenhouse gas. Like **carbon dioxide**, methane traps heat reflected from the earth and, therefore, may contribute to global warming. Increases in agricultural and dairying activities have resulted in an increase in methane production, possibly contributing to **climate** change. *See also* Greenhouse effect; Greenhouse gases

Methane digester

Methane digesters are systems that use anaerobes to produce methane through fermentation. Methane is a main constituent of **natural gas** and can be readily substituted for that nonrenewable resource.

The anaerobes used in methane digesters are methanogenes, bacteria belonging to the genera *Methanobacterium*; *Methanosarcina*; and *Methanoccus*. They can be found in the gastrointestinal tracts of animals such as cows and other ruminants, as well as in **soil**, water, and sewage. In septic tanks, bacteria liquefy some of the organic matter; which releases energy for the bacteria and by products such as methane and **carbon dioxide**.

Methane digesters are also known as biogass digesters and organic digesters. The central portion is an airtight drum, called a digester unit, which contains the methanogenes. Raw material is place into the drum, and the unit is kept at a constant temperature of about 95˚F (35˚C). Some of the methane produced by the digester heats the water. Outlets on the digester unit take away the various products of the system. Liquid and solid fertilizers are collected to be used for crops and other plants. Methane is stored in a tank, from which it can be drawn off for fuel for a variety of purposes. **Carbon** dioxide and **hydrogen** sulfide can be filtered out of the methane and put under pressure for use in turning turbines.

Common household organic wastes can be put into a digester, and the methane produced can be used to make electricity. It can also be used for cooking, illumination, heating, and **automobile** fuel. One system at the University of Maine produced over $8,000 worth of power a year in the early 1990s; the digester also produced a **sludge** that could be used as a nutritious and relatively odorless plant **fertilizer**. Some sludges, however can contain high level of metals if the original material is unsorted municipal waste.

Methane is a clean and nontoxic automobile fuel, and it produces no pollutants when burned. It has an octane number of 130. Italy has used it as a motor fuel for over 40 years, and Modesto, California, has a small fleet of methane-powered cars. Because of its cleanliness, it extends the life of engines as well as making starting easier.

The organic matter this system converts into other uses would otherwise have decomposed in a **landfill**, **leaching** into the surrounding **environment** and contaminating **groundwater** supplies. In a digester, it becomes a useful resource. *See also* Alternative energy sources; Alternative fuels; Anaerobic digestion; Bioremediation; Groundwater pollution

Methanol

Methanol is an organic compound with the chemical form CH_3OH. It is also known as methyl alcohol or wood alcohol. Like most alcohols, methanol is very toxic. Its ingestion can cause severe nerve damage leading to blindness, insanity, and death. Methanol can be prepared through destructive distillation of **coal**, wood and wood products, **garbage**, sewage **sludge**, and other forms of **biomass**. It is an excellent automotive fuel and has long been used to power racing cars. Existing methods of production are still too expensive, however, to make it an economically viable alternative to **gasoline** in the general market. *See also* Alternative fuels; Fuel-switching

Methyl tertiary butyl ether

Methyl tertiary butyl ether (MTBE) is a flammable, volatile, and colorless liquid fuel additive that is manufactured by the chemical reaction of **methanol** and isobutylene. It is one of a group of **chemicals** referred to as oxygenates, because they raise the level of oxygen in **gasoline**. Oxygen helps gasoline burn more completely, thus reducing emissions.

MTBE has a strong odor similar to a general anesthetic. Humans can detect it by smell at very low concentrations: 53 **parts per billion** (ppb) in air and 20 to 40 ppb in water. MTBE is very soluble in water and more soluble than other gasoline constituents. It is also persistent and resistant to degradation.

As a gasoline additive, it is used to increase the octane level (replacing the use of **lead** additives) and to reduce vehicular emissions of **carbon monoxide** (CO) and ozone-forming pollutants. It was first used in the United States in

the 1970s, with its use increasing during the 1990s, when the **Clean Air Act** Amendments of 1990 created the Oxygenated Fuel Program. Areas of the country with severe **air pollution** problems are required to add oxygenates to gasoline during winters to reduce vehicular emissions of CO. Although regulatory requirements do not specify the types of oxygenates required, MTBE and **ethanol** are the main oxygenates used. Ethanol is the primary oxygenate used in the Winter Oxyfuel Program. Areas with problems meeting **ozone** standards require the use of reformulated gasoline (RFG) year round to reduce ozone-forming pollutants. RFG is oxygenated gasoline (with a minimum of 2% oxygen by weight) that is specially blended to have fewer polluting compounds than conventional gasoline. As the addition of ethanol increases the vapor pressure of gasoline such that it is difficult for ethanol-containing gasoline to comply with summertime volatility requirements, MTBE has been the preferred oxygenate for use during the summer. In 1970, MTBE was the 39th-highest produced organic chemical in the United States; by 1998, it was the 4th-highest produced organic chemical. In 1999 over 200,000 barrels of MTBE per day were produced.

The use of RFG has improved the quality of air in the United States. The U.S. **Environmental Protection Agency** estimates that smog-forming pollutants are being reduced annually bey at least 105 million tons and toxic chemicals by at least 24 million tons.

However, the success of the **air quality** program that utilizes MTBE to reduce emissions has been offset by contamination of ground and surface waters with MTBE. MTBE has been detected in **soil**, surface water, and ground water throughout the United States. Point sources of MTBE include releases from underground and above-ground storage tanks and pipelines due to leaks, overfilling, and faulty construction. Non-point sources of MTBE include **urban runoff**, precipitation, vehicle accidents, and motorized water craft. MTBE may also be released to the **environment** through gasoline fumes during vehicle refueling. A study by the U.S. **Geological Survey** in 1993–1994 showed that MTBE was the second most frequently detected volatile organic chemical of 60 chemicals in samples collected from shallow ground water in eight urban areas. Another report in 1999 by the U.S. Environmental Protection Agency's Blue Ribbon Panel on Oxygenates in Gasoline indicated that between five and ten percent of drinking water **wells** in areas with high use of MTBE had detectable levels of MTBE, while one percent had levels higher than 20 micrograms per liter. During the summer of 1996, the City of Santa Monica in California stopped pumping ground water from two of its well fields because of persistent and increasing levels of MTBE. These two wells provided about 50% of the city's drinking water supply.

MTBE has been shown to have the potential to produce adverse effects associated with central nervous system depression, including headaches, dizziness, nausea, and disorientation. These effects are reversible if exposure is discontinued. Evidence from animal studies suggests that MTBE is a potential human **carcinogen**. When it enters the human body through inhalation or **absorption** through the skin, it may metabolize into two compounds, tertiary butyl alcohol and formaldehyde, that are carcinogenic in animals and are also classified as potential human carcinogens.

In 1997 the U.S. Environmental Protection Agency issued a Drinking Water Advisory for MTBE. The Advisory recommended that the levels of MTBE in drinking water by limited to 20 to 40 micrograms per liter. This limit was set to assure consumer acceptance with regards to taste and odor and to provide an adequate margin of safety from toxic effects. Based on this Advisory, several states have set their own drinking water standards for MTBE. A nation-wide standard for MTBE under the **Safe Drinking Water Act** is not expected until after February 2005, due to lack of information regarding health effects and occurrence data. In March of 2000, the U.S. Environmental Protection Agency formally began regulatory action to eliminate or phase down MTBE, issuing an Advance Notice of Proposed Rulemaking under Section 6 of the Toxic Substances Control Act, which gives the U.S. Environmental Protection Agency authority to ban, phase out, limit or control the manufacture of any chemical substance deemed to pose an unreasonable risk to the public or the environment. The State of California is considering a ban on the use of MTBE by the end of 2003. As of 2002, bans on MTBE are also under consideration in at least 16 other states. Research is being conducted to develop alternative oxygenates so if MTBE is banned, air quality benefits of the use of oxygenated fuels will be preserved.

Because of its physical properties, during a release MTBE migrates rapidly through the soil column. Upon reaching the ground water, MTBE moves at the same velocity as water and faster and farther than other gasoline constituents. As the gasoline contaminant **plume** degrades over time, **benzene**, **toluene**, ethyl benzene, and **xylene** (BTEX) decrease in concentration more than MTBE, which is more resistant to degradation. Eventually MTBE may be the only contaminant remaining from the release.

The extent of MTBE contamination in the subsurface has led to the investigation of treatment technologies. If MTBE in soil is not dissolved in water, it can be removed by such treatment methods as soil vapor extraction. However, the high solubility of MTBE in water and its **resistance** to degradation makes it difficult and time consuming to remove from ground and surface waters using many common remedial technologies. Promising technologies for re-

moval of MTBE that are being studied include chemical oxidation using ultraviolet light and **hydrogen** peroxide, **phytoremediation** using deep-rooted trees, and cometabolic degradation processes.

Methylation

A chemical reaction in which the methyl radical (-CH_3) is added to some substance. The most common mechanism by which methylation occurs in the **environment** is **biological methylation**, which involves the action of living organisms. Bacteria in oxygen-poor soils, for example, can convert metallic **mercury** to an organic compound, methyl mercury. Similar reactions occur with other metals, including **arsenic**, selenium, tin, and **lead**. These reactions are significant because they convert non-soluble metals of low toxicity into soluble forms with high toxicity. Light can also induce methylation. Photomethylation has occurred in the laboratory, but its relative importance in environmental systems is not yet well understood.

Methylmercury seed dressings

Seed dressings were devised to prevent diseases caused by a wide variety of seed-borne plant-pathogenic **fungi**, to protect the germinating seeds against secondary infections, and to increase crop yields. Various **chemicals**, including several **heavy metals**, have been used as fungicides to treat seeds since the end of the nineteenth century. The effectiveness of these fungicides was greatly increased when aryl organomercurials were introduced around 1914. They had a wider spectrum of fungicidal activity than nonmercurial formulations and were used extensively until the mid-1980s to control fungus diseases through their application as seed dressings on many grains, vegetables, and nuts, as well as to protect fruit trees, rice, turf grasses, and **golf courses**. However, with the introduction of the more effective alkyl **mercury** compounds in the 1930s, especially methyl mercury and ethyl mercury, severe **poisoning** incidents followed. In developing countries hundreds of people died or became incapacitated due to either the consumption of grains treated with alkylmercury compounds or meat from animals that had eaten such treated seeds.

Poisonings from eating alkylmercury-treated grains occurred on several occasions in various parts of Iraq. Destitute, illiterate rural families either did not understand the words or poison symbols on the bags of grain or did not believe government warnings that it was unsafe to eat. In some instances the families fed some of the grain to chickens and swine first. When they did not observe poisoning symptoms in the livestock and poultry after a few days, the farmers became convinced that the warnings were false and the grain was safe to eat. However, depending on the amount of methyl mercury consumed, there is a **latency** period of weeks or months between exposure and the development of poisoning symptoms.

When the seed grain was ground into flour, baked into bread, and consumed by the rural victims, both sexes and all ages were affected. The ingested quantities of methylmercury ranged from small amounts that produced no overt effects to lethal doses. Fetuses suffered the most damage. Among the rest of the population, the severity of the neurological and psychiatric symptoms was almost directly proportional to the amount of bread consumed. In cities where bread was produced from government-inspected flour mills, not a single case of poisoning was reported.

The first documented incident occurred in Iraq in 1956. Of the two hundred persons afflicted, seventy died. In 1960 an estimated 1000 persons were affected in a similar incident and over 200 died. During the 1960s other smaller but similar episodes of alkylmercury poisoning occurred on a more limited scale in West Pakistan, Guatemala, Ghana, and in other countries such as Mexico and the United States. The total death toll in these countries was 42 with approximately 197 individuals less seriously affected.

But the most serious outbreak of poisoning from eating methyl mercury-poisoned bread occurred in Iraq early in 1972. In October and November of 1971 a total of about 73,000 tons of high-yield Mexipac wheat seed grain and 22,000 tons of barley seed grain, all treated with alkyl mercury **fungicide**, had been distributed by cooperatives to farmers for planting throughout the country. Some of this grain, as before, was used to prepare homemade bread. The Iraqi government estimated that the treated grain was distributed to no more than five percent of the rural population, about 200,000 people. Most of the fatalities occurred within three months after the end of the exposure, although a few long-term illnesses resulted in fatalities as well.

By March 1973, up to 40,000 persons, residents of every province, were unofficially estimated to have been poi-

soned. The total number of casualties will never be known precisely because hospitals were quickly overloaded, and many victims did not have access to them. In addition, most of the poisonings occurred in rural areas, and many were not reported to authorities. The government officially acknowledged that 6,530 persons were hospitalized and 459 died. These figures were not confirmed because news reporters were denied entry to the country and the movements of foreigners were restricted. However, tourists reported that large numbers of Iraqis suffered brain damage, blindness, and paralysis. Since then, with the exception of a few follow-up scientific reports published between 1985 and 1989, hardly any new information relative to the long term health effects on the thousands of victims has been published or released by the Iraqi government although this was the largest such tragedy of this kind. Because of the highly toxic nature of the alkyl mercurials, as well as the severity of the accidents caused by misuse of the treated seeds, they were banned in 1970 in the United States and many other countries. *See also* Agricultural chemicals; Birth defects; Heavy metals and heavy metal poisoning; Minamata disease; Plant pathology; Teratogen; Xenobiotic

Mexico City, Mexico

Founded in the fourteenth century, Mexico City has been a center for three great civilizations: the Aztecs, the Spanish, and the modern-day Mexicans. But in addition to an imposing political background, its geographical location has assured the city a fascinating ecological and **environmental history**. Mexico City lies in a basin 7,350 feet (2,240 m) high. It is surrounded by mountain ranges on all sides, and the presence of the extinct volcanoes Ixtacihuatl and Popocatepetl to the east are a reminder that the city lies on an active **earthquake** fault.

Most of Mexico City's environmental problems are caused by a combination of its geographical location and growing population. In 1900, the population was estimated at 350,000; the rest of the century has seen nothing but rapid growth. Population has leapt from 1,029,000 in 1930 to 4,871,000 by 1960, and then to 12,000,000 in the mid-1970s, and then 15,000,000 by 1981. According to some estimates, Mexico City will have more than 32 million inhabitants by the year 2000, making it the most populous urban area in the world.

The amount of **pollution** produced by a city of this size would be difficult to control in even the most favorable geographic circumstances. But the basin in which Mexico City is built traps the **ozone**, **nitrogen oxides**, sulfur, and particulates that are released each day. Soft **coal**, wood, and low-grade **gasoline** and oil are burned widely throughout the city, contributing greatly to this problem. In addition, prevailing winds from the northeast carry dust particles into the city from rural areas, further degrading **air quality**. The city has gone from having one of the most perfect natural settings and ideal climates in the world to being the most heavily polluted. Pollution levels can rise so high that schools are occasionally forced to close so students can remain indoors and not breathe the polluted air. Entrepreneurs have even set up booths on city streets where people can pay to breath oxygen from tanks.

Lying near the boundary of the Pacific and North American geological plates, Mexico City has long been at risk for major earthquakes, a risk which has been greatly increased by the city's history. When the Aztecs first settled the area, it was largely covered by an enormous lake, Lake Tenochititlán, which either was filled in or dried out as the city began to grow. Today, Mexico City sits on a soft **subsoil** that is highly unstable. Some parts it are actually sinking into the old lake bed, while the whole area rides out each earthquake like a boat on an unsettled ocean.

The geographical instability of the area has been worsened by the fact that residents traditionally obtain their water from **wells**. As the population grows, more water is removed and **subsidence** increases. In some parts of the old city, buildings have actually sunk more than 6 ft (2 m) below street level. Since measurements were first made in 1891, subsidence in some areas has exceeded 26 ft (8 m), and it measures at least 13 ft (4 m) in nearly all parts of the city. *See also* Air pollution control; Air quality criteria; Los Angeles Basin; Nitrogen cycle; Population growth; Sulfur cycle; Sulfur dioxide

Microbes (microorganisms)

Microbes, also known as microorganisms, are defined solely on the basis of their size—they are too small to be seen by the naked eye. Microorganisms can only be viewed if they are magnified in size, using an optical or electron microscope.

Apart from their size, the major groups of microorganisms have little affinity in terms of their evolutionary history and systematics. Included among the microorganisms are viruses, bacteria, blue-green bacteria, some algae, some **fungi**, yeasts, and protozoans.

Viruses

Although viruses are commonly considered to be microorganisms, they are actually "pseudo-organisms" because they do not display all of the characteristics of life. Viruses consist only of bits of **nucleic acid** (either deoxyribonucleic **acid** (DNA), or **ribonucleic acid** (RNA)) surrounded by a protein capsule (called a capsid). Viruses are not capable of independent reproduction, and they cannot perform other important metabolic functions. To reproduce and grow viruses must invade and parasitize the living cells of other organisms, and appropriate the metabolic capabilities of their host.

It is probable that all living cells are infected by viruses of various sorts, and in some cases serious diseases are caused. Viral diseases of humans include colds, flu, and more deadly ailments such as smallpox, yellow fever, rabies, herpes, polio, and human immunodeficiency syndrome (HIV, also known as **AIDS**). Some viral diseases can be controlled by vaccination, a practice that involves infecting hosts with killed but intact **virus** bodies. These are non-virulent but nevertheless cause the host to develop **resistance** to pathogenic forms of the strain. Vaccination made it possible to achieve the eradication of smallpox, a disease that had long been a scourge of humans.

Bacteria and Blue-green Bacteria

Bacteria and blue-green bacteria are in the kingdom of life known as Monera. Most **species** in this group are

bacteria; these have rigid or semi-rigid cell walls, propagate by binary division of the cell, and do not display mitosis during cell division. Blue-green bacteria or cyanobacteria (sometimes incorrectly referred to as blue-green algae) utilize chlorophyll dispersed within their cytoplasm as a pigment for capturing light energy during **photosynthesis**. The genetic material of monerans is organized as a single strand of DNA, and it is not contained within a membrane-bounded organelle called a nucleus, so these microorganisms are referred to as being prokaryotic. (All of the other kingdoms have a nucleus within their cells, and are known as eukaryotic.) In addition, prokaryotes do not display meiosis or mitosis, their reproduction is by asexual cellular division, and they do not have organelles such as chloroplasts, mitochondria, or flagella. Prokaryotes were the first organisms to evolve, about 3.5 million years ago. It was not until 2 million years later that the first eukaryotes evolved.

About 4,800 species of bacteria have been named, but microbiologists believe that there are many additional species that have not yet been discovered. Bacteria are capable of exploiting an astonishing range of ecological and metabolic opportunities. Some species can only function in the presence of oxygen, and others only under **anaerobic** conditions, although some species are able to opportunistically switch between these metabolic types. Some bacteria can tolerate very extreme environments, surviving in hot springs at temperatures as hot as 172°F (78°C), while other species have been found active in the frigid conditions that occur as deep as 436 yd (400 m) in glaciers.

Most free-living bacteria are heterotrophic, and among the diversity of bacterial species are some that are capable of metabolizing virtually any organic substances as a source of nutrition. Other species of bacteria are photosynthetic (including blue-green bacteria), capable of capturing sunlight and using it to reduce **carbon dioxide** and water into simple sugars, which are used as a source of energy in more complex biochemical syntheses. Other bacteria are chemosynthetic, coupling their biosynthetic abilities to energy released during the oxidation of certain inorganic compounds, as when pyritic sulfur or sulfide are oxidized to sulfate.

Many species of bacteria are not free-living, and instead live in a mutualistic **symbiosis** with more complex organisms, such as plants or invertebrate or vertebrate animals. For example, numerous species of bacteria live as a microbial community within the rumen of cows and sheep, while others live in the gut of humans and other primates. These gut bacteria help with the digestion of complex organic foods, and they also synthesize vitamins and micronutrients that are useful to their host. Other bacteria in the genus *Rhizobium* live in a **mutualism** with the roots of peas, clovers, and other leguminous plants, fixing atmospheric dinitrogen gas (N_2) into ammonia (NH_3), which after conversion to ammonium (NH_4), it becomes a source of **nitrogen** that plants can utilize as a **nutrient**.

Many bacteria are **parasites** of other organisms, and some cause important diseases. Significant diseases of humans caused by bacteria include various kinds of infections, bacterial pneumonia, **cholera**, diphtheria, gastric ulcers, gonorrhea, Legionnaire's disease, leprosy, scarlet fever, syphilis, tetanus, tooth decay, tuberculosis, whooping cough, most types of food **poisoning**, and the "flesh-eating disease," which is caused by a virulent strain of *Streptococcus*. Bacteria also cause diseases of other species, and this is sometimes used to the advantage of humans. For example, **Bacillus thuringiensis** is a pathogen of many species of moths, butterflies, and blackflies, and strains of this bacterium have been used as a biological insecticide against certain insect pests in agriculture and forestry.

Microscopic Protists

The kingdom Protista consists of a wide range of simple eukaryotic organisms, including numerous unicellular and multicellular species. Microbial protists include protozoans, foraminifera, slime molds, single-celled algae, and multicellular algae. (Some other multicellular algae are not microscopic—the largest seaweeds, known as kelps, can grow fronds longer than 11 yd [10 m]!) Eukaryotic organisms have their genetic material organized within a membrane-bounded nucleus, containing paired chromosomes of DNA. Protists have flagellated spores, and mitochondria and plastids are often, but not always, present.

Recent systematic treatments have divided the kingdom Protista into about 14 phyla, consisting of about 40,000 named species. Many of these phyla, however, differ enormously from the others in basic elements of their biology. It is likely that additional systematic research of this extremely diverse group will result in the Protista being divided into several kingdoms.

Several phyla of protists are photosynthetic, and these are collectively known as algae. Most species in the following groups are microscopic: diatoms (phylum Bacillariophyta), green algae (Chlorophyta), dinoflagellates (Dinoflagellata), euglenoids (Euglenophyta), and red algae (Rhodophyta). The brown algae and kelps (Phaeophyta) are macroscopic, as are some colonial species in several of the other groups. Algae are important primary producers in marine and freshwater ecosystems. Uncommon phenomena known as "red tides" are natural blooms of certain species of marine dinoflagellates that produce toxic biochemicals.

Other phyla of microbial protists have a heterotrophic nutrition. Protozoans are single-celled microorganisms, generally considered to be microscopic animals. Protozoans reproduce by binary fission, and are often motile, usually using cilia or flagella for propulsion. Some protozoans are colonial. Protozoans are abundant in most aquatic environments.

Other heterotrophic protists include the ciliates (Ciliophora), forams (Foraminifera), amoebae (Rhizopoda), and unicellular flagellates (Zoomastigina). Forams are unicellular microorganisms that form a "shell" of calcium carbonate. Chalk is a mineral that is formed from the remains of forams that have accumulated over geologically long periods of time. (The white cliffs of Dover, England, consist of the fossil remains of innumerable forams).

Some species of protists cause diseases of humans, such as *Plasmodium*, a unicellular blood parasite that causes **malaria** and is spread to people and other vertebrate animals by mosquitoes. Some species of amoebae are parasites of animals, causing amoebic dysentery in humans. Hiker's diarrhea (or beaver fever) is a water-borne disease caused by the ciliate *Giardia*, which is the reason why even the cleanest-looking natural waters should be boiled or otherwise disinfected before drinking.

Microscopic Fungi

The kingdom Fungi consists of single-celled microorganisms known as yeasts, plus the fungi, which are multicelled, filamentous in their growth form, and reproduce by budding or by cellular fission. All yeasts and fungi are heterotrophic, excreting enzymes that digest complex organic materials, allowing simple organic compounds to be ingested.

A few species of yeasts are economically important because they have the ability to ferment sugars under anaerobic (O_2-deficient) conditions, yielding gaseous CO_2 and ethyl alcohol (or **ethanol**). The CO_2 produced during fermentation can be utilized to raise bread dough prior to baking, while the alcohol can be used by brewers to produce beer, wine, and other intoxicating beverages.

Microorganisms are characterized only by their microscopic size. Otherwise they comprise a wide range of diverse but not necessarily related groups of organisms. As a larger group, microorganisms are extremely important as primary producers in ecosystems, as agents of decay of dead organisms and **recycling** of the nutrients contained in their **biomass**, and as parasites and diseases of humans and other species.

Microbial pathogens

Microbial pathogens are **microorganisms** that are capable of producing disease. Virtually all groups of bacteria have some members that are pathogens. One notable exception is the Kingdom Archaea, where there are no known pathogenic members. Other disease-causing microbial agents are viruses and parasitic protozoa. Earlier methods of detecting and identifying microbial pathogens involved culturing and isolating bacterial colonies in growth media in the lab. With the advent of polymerase **chain reaction** (PCR) assays, identification of microorganisms that were difficult or impossible to culture became possible. Many microbial pathogens can be controlled with antimicrobial drugs called antibiotics. However, these drugs are not effective against viruses or **parasites**, and indiscriminant use may cause resistant strains of pathogens to evolve. **Antibiotic resistance** has resulted in the reemergence of several disease, and as of 2002, most of the major bacterial diseases that infect humans are becoming resistant to antibiotics.

[*Marie H. Bundy*]

Microclimate

In general, **climate** conditions near the ground are called microclimates. More specifically, microclimate refers to the climate characteristics of highly localized areas, ranging from the area around an individual plant to a field of crops or a small forested area. The horizontal area considered may be less than one square meter or up to several thousands of square meters. The vertical extent may range from a few centimeters involving the still layers of air within a plant canopy, for instance, to 100 meters or more, when the **atmosphere** surrounding a forested area is studied.

Microclimates are governed to a large extent by the interactions of surface features with the overlying atmosphere, and their characteristics may differ markedly from those of the surrounding large-scale climate. Microclimates exhibit great ranges in environmental conditions depending on the moisture and radiation properties of the surface. They typically show large diurnal temperature ranges and are highly influenced by slope, aspect, and elevation. Most plants and animals are adapted to highly specific microclimatic conditions.

Micronutrient

see **Trace element/micronutrient**

Migration

Although some scientists define animal migration as any animal movement, this definition becomes cumbersome because it does not distinguish between small-scale daily movements, annual migrations, and irrupting dispersions. Mobile animals tend to move frequently, and migration should be distinct from emigration (directional one-way movement) and dispersal (non-directional one-way movement), and it should refer primarily to regular round trip movement that happens at least once in the life span of the organism. Migration is a spatial behavior pattern that allows animals to locate themselves in the most favorable portions of their **habitat** for as long as necessary. Such favorable conditions may vary according to season or life history, but in both cases it is related to adaptive fitness. This allows the organism to take in nutrients in excess of energy expenditures and to successfully reproduce.

Generally animal migration can be divided into two areas of study: the behavioral aspects, which concentrates on "how" migration happens; and the ecological aspects, which addresses "why" migrations takes place. The ecological questions also concern **evolution**, for spatial behavior is an evolved compromise between differing requirements of an organism's life. Most migratory behavior depends on food abundance. In most habitats productivity varies with the seasons, and thus energy availability also varies at all upper levels of food chains. Migration must often accommodate several energy and reproductive requirements. As a result migration patterns tend to be complicated with subsections of migrants taking slightly differing paths at various times to serve different needs.

Many **species** of North American waterfowl use several breeding areas, from the northern prairies to the Arctic coast, and travel along several major flyways to wintering areas that range from the southern prairies to the estuaries of northern South America. Within that framework, males **desert** the hens during nesting season and make shorter migrations to molting areas, afterward meeting with the females and newly fledged young during the fall migration. In either of those sites, requirements for habitat differ in terms of water-cover ratios, water permanence, and food preferences.

The altitudinal migration of mountain sheep (*Ovis canadensis*) in the Rocky Mountains brings them into more productive habitats during the summer in the alpine meadows and into the mountain forest during the winter. Thus, food intake requirements are accommodated and, simultaneously, the sheep take advantage of the **microclimate** of the forested area during the winter to supplement energy losses from body temperature maintenance.

Migration can also be a response to particular breeding site requirements, mate location, and a combination of several forces acting together. The longest mammal migration, that of the California gray whale (*Eschrichtius robustus*), places the breeding-ready adults and newly impregnated females in the productive shallows of the Bering and Chukchi Seas, the non-breeding animals in the more patchy feeding grounds of the northeast Pacific Coast, and the calving females in the warm shallow lagoons of the Baja Peninsula.

Milankovitch weather cycles

According to the theory of the Milankovitch weather cycles, ice ages are cyclical, caused by changes in the earth's orbit. The theory was developed by Serbian geophysicist Milutin Milankovitch (1879–1958) in the 1930s, and it postulates that the amount of available sunlight in the northern hemisphere is affected by the earth's orientation in space. Because the earth is a globe in motion, sunlight strikes the earth differently depending on the following factors: The eccentricity of its orbit, which returns to the same point every 100,000 years; the tilt of the axis of its rotation, a 41,000-year cycle; and the precession of the equinoxes, a 23,000-year cycle. Milankovitch proposed that decreased sunlight prevents ice and snow from melting in the summer in the northern latitudes. This, in turn, cools the **atmosphere**, because ice reflects 90 percent of solar radiation back into space, and over a long period of time, the ice accumulates and moves south.

The theory has gone through its own cycles of acceptance and rejection. The first problem for proponents of the theory was to prove the occurrence of glacial-interglacial patterns during the Pleistocene era, the epoch preceding ours. It was also necessary to date the onset of each **ice age** in order to calculate the date of the next one. During the last fifty years, data collection improvements in astronomy and geology, especially in satellites and deep-sea **sediment**

coring, have challenged and refined the theory. Supported first by astronomical and geological data, the theory encountered opposition in the 1950s when scientists used the newly-developed Carbon-14 method to date warm-era fossils in supposed ice-age deposits. But examination of fossilized microscopic sea creatures on the ocean bed, known as foraminifera, revealed two types, the larger of which flourished when the ocean was warm. In 1955, geologist Cesare Emiliani refined dating techniques of the foraminifera retrieved by deep-sea coring. He isolated oxygen isotopes. Oxygen 16, a lighter **isotope**, evaporates more quickly and becomes trapped in ice, while oxygen 18, which thrives in warm waters, was absorbed by the shells of the foraminifera. From the evidence of theses oxygen isotopes, Emiliani was able to reconstruct glacial-interglacial periods for 300,000 years. His date agreed with Milankovitch's orbital dates.

In 1971 John Imbrie of Brown University created Project CLIMAP, which coordinated all of the data relevant to Milankovitch's cycles. From this data, scientists were able to develop a "rosetta stone" for Pleistocene glacial-interglacial dates. In the 1980s, Project SPECMAP brought together all of the deep-sea core data. It was from this data that scientists predicted the next ice age was imminent.

But critics have argued that the Milankovitch orbital theory does not take into account the concept of chaos as well as the climatic influence of the heat transfer between the atmosphere and the ocean. In 1992, United States **Geological Survey** hydrogeologist Isaac Winograd challenged the Milankovitch theory when a scuba team with a submersible drill retrieved a 14-in (36-cm) core of calcite in a water-filled fault called Devils Hole in Nevada. The ice age dates for this core of calcite differed from the Milankovitch dates, and this suggested to Winograd that ice ages were tied less to orbital cycles than to an interaction of heat and moisture between the atmosphere, the ocean, and ice sheets. Imbrie and many others defended Milankovitch against these findings. They stood on their mountain of ocean-sediment core data, and they argued that the calcite core from Devils Hole reflected local rather than global changes.

Another problem for the Milankovitch theory is identifying the effects of human activity on the **environment**. The current interglacial period began 10,000 years ago, and according to Imbrie, it might become a "super interglacial" period due to the burning of **fossil fuels** and the subsequent **greenhouse effect**. Imbrie has argued that the natural cooling cycle which began 7,000 years ago will be postponed until the excess **carbon dioxide** is exhausted in 2,000 years. Then, after another 1,000 years, serious cooling will set in, expected to last for 23,000 years. *See also* Climate; Glaciation; Ice age refugia; Ozone layer depletion; Radiocarbon dating

Minamata disease

The town of Minamata, near the southern tip of Japan's Kyushu Island, gave its name to one of the most notorious examples of environmental contamination known. Minamata disease is really alkylmercury **poisoning**, caused by eating food such as fish or grain contaminated with **mercury** or its derivatives. At Minamata people were poisoned when they ate large quantities of methylmercury-contaminated fish. Often the victims were the poorest members of society, who could not afford to stop eating the cheap fish known to be affected by **effluent** discharged from the local chemical company. The first victims were reported in 1956; before that, cats were seen moving strangely, sometimes flinging themselves into the sea, and birds were observed flying awkwardly or even falling out of the sky.

The Chisso Company, a leading chemical manufacturer, produced acetaldehyde by passing acetylene gas across an inorganic mercury catalyst, leaving methylmercury as a by-product. The company was a major local employer and the only significant major source of industrial waste discharged into Minamata Bay. There, methylmercury in the water biomagnified to high levels in fish and shellfish consumed by the local inhabitants. Methylmercury concentrates in specific regions of the central nervous system and readily crosses the blood/brain barrier as well as the placental barrier. It is a human **teratogen** which causes brain damage during prenatal exposures, resulting in congenital or fetal Minamata disease. The compound has a **half-life** of about 70 days in the human body, and the damage is generally irreversible. Although company officials knew that similar symptoms could be induced in cats by feeding them fish taken from the bay, Chisso was not blamed by the Japanese government

A mother from Minamata, Japan, bathes her daughter who suffers from Minamata disease. The daughter's brain damage and birth defects were caused by alkylmercury poisoning from mercury-contaminated seafood that her mother ate while pregnant. (Photograph by Eugene Smith. Black Star Publishing Company Inc. Reproduced by permission.)

for the disaster until 1968. Despite the evidence, it was difficult to be certified as a Minamata disease victim. Those affected were not compensated until after another epidemic occurred at Niigata, Japan, in 1965. That one was caused by methylmercury waste discharged from the Showa Denko Corporation Kanose factory into the Agano River. The company also manufactured acetaldehyde using the same process as Chisso.

Nearly four decades after Minamata disease was identified, the full range of its neurological symptoms is still not known, nor have the total number of sufferers been determined. While some children were born with contorted bodies and severe retardation, in milder cases the victims may be moderately retarded or exhibit only sensory disturbances. Even as the symptoms advance in adult patients, it is often difficult to determine whether they are the result of long-term poisoning, delayed effects of residual methylmercury, aging, or other complications. Therefore, even thirty years later, as of December 31, 1992, only 2,945 individuals were officially certified as Minamata Disease victims and 1,343 of them had died. Another 13,761 had been denied certification and the fate of 2,430 was still pending.

Lawsuits dragged on for more than twenty-five years, and victims seeking compensation tried confrontation tactics like an encampment that lasted a year and a half in front of Chisso's main headquarters in Tokyo. **Reclamation** of the **environment** has been even slower. The Chisso Company installed waste treatment equipment in 1966 and stopped making acetaldehyde in 1968. By then 400–600 tons of mercury and 60,000 tons of **sludge** had been dumped into the shallow Minamata Bay. Mercury levels in fish remained elevated. **Dredging** scheduled to begin in 1975 did not get underway until 1982. Since then, mercury levels in ten **species** of fish have dropped; but as of March 1993, they were still two or three times higher than what the government deems acceptable. Consequently, fishermen have lost their livelihood and health and gained a social stigma. The Chisso company's fortunes also declined and were further strained by lawsuits that mandated restitution. *See also* Agricultural chemicals; Biomagnification; Birth defects; Envi-

ronmental law; Food chain/web; Heavy metals and heavy metal poisoning; Marine pollution; Methylmercury seed dressings; Water pollution; Xenobiotic

Mine drainage

see **Acid mine drainage**

Mine spoil waste

Most human extractions of earth materials, such as clay for pottery or **coal** for power generation, produce some waste. The raw materials are rarely pure, so unwanted **detritus** is discarded, usually close to the extraction site. Over the last two centuries, exponential industrial growth has resulted in huge increases in the production of mine **spoil** waste. The management of this waste has become an increasingly important issue.

New technologies allow the mining of ever lower grades of ore, with mounting waste as a byproduct. Early mining actually wasted ore, since only the richest veins were extracted. However, less waste was generated by this high grade ore. Now operations tend to remove varying grades of ore *en mass*, yielding a higher return, but multiplying the waste produced. Where concentrations are high, it has even been profitable to rework older **tailings**.

Surface mining accounts for most mining waste, but underground work also contributes. Metallic ores, sand, gravel, and building stone, including aggregate for concrete, are usually extracted from open pit mines. **Strip mining** is effective where resources lie in sedimentary layers, and is particularly used for coal, phosphate, and gypsum. Much of the waste from strip mining comes from **overburden** removal. **Dredging** is used to extract sand and heavy placer deposits such as gold and tin; it reinjects large amounts of fluvial **sediment** into the flowing water. Hydraulic mining with high pressure hoses is common in gold fields; devastating effects are still visible in the foothills of California's Sierra Nevada Mountains, more than a century later.

Environmental impacts of mining include the creation of new landforms, severe **ecosystem** disruption, and the formation of dangerous **chemicals**. The scale of operation varies enormously, but some projects are immense. The holes and mountains of overburden created may become useful as chat for railroad beds, sub-base material for roads, or recreational lakes. But, severe environmental problems are a more common result. Ecosystem disruption stems mainly from loss of **topsoil**, rich in organisms and nutrients; sterile landscapes with high sediment **runoff** are a common outcome.

The most serious problem resulting from mine wastes is **acid drainage** and **leaching** of hazardous substances. When these wastes are moved from a reducing **environment** (oxygen deficient) to an oxidizing environment, sulfuric acids are formed by the oxidation of the sulfides in metallic ores or the sulfur that commonly accompanies coal deposits. These acids may flow into surface waters or may leach hazardous metals from the waste. The best solution is to minimize exposure to oxygen, usually by burial.

Mining presents the dilemma of short term gains versus long term losses, especially of land suitable for agriculture or forestry. The goal of sustainability makes **reclamation** of mine spoil wastes imperative. *See also* Acid mine drainage; Erosion; Hazardous material; Sustainable development; Waste management

Mineral Leasing Act (1920)

The Mineral Leasing Act of 1920 regulates the exploitation of fuel and **fertilizer** minerals on the public lands. The act resulted from the perceived failure of existing federal laws dealing with **coal** and oil resources. Coal lands had been managed under an 1873 law, allowing the coal to be mined for either $10 or $20 per ton on tracts of 160 or 320 acres (64.8 or 129.6 ha). These acreage limitations led to abuse of the law, and in 1906 over 65 million acres (26.3 million ha) of land were withdrawn from coverage under of the coal lands law. These lands were then reclassified according to

whether they contained coal or not, and the price for lands containing coal was increased. The withdrawal and reclassification process slowed development and led many to argue for a new approach. The fate of these coal lands was soon tied to the fate of oil lands.

Oil resources were being managed based on the Mining Law of 1870 and the Oil Placer Act of 1897. Neither law, however, sufficiently recognized the difference between **petroleum** and other minerals this in turn resulted in major problems in the exploitation of petroleum. These problems included overproduction, market instability, claim jumping, and national security concerns. In 1909, President William Howard Taft withdrew over three million acres of **public land** from oil development in California and Wyoming, thereby initiating a policy debate over how to manage petroleum resources on the public lands.

The first leasing bill, supported by the Taft administration, was introduced in Congress in 1913, but because it was so controversial in the western states, the Mineral Leasing Act was not passed until 1920. The law, which applies to deposits of coal, oil, gas, **oil shale**, phosphate, potash, sodium, and sulfur on the public lands, has two main features: federal regulatory authority and conditional access to the public lands. Controversy centered on the oil provisions of the Act. These gave the Secretary of the Interior the authority to issue permits for prospecting on land that was not known to have any oil. If oil were discovered, the prospector acquired lease rights for 20 years and paid a royalty fee of five percent. For proven oil-producing lands, tracts were offered under a system of competitive bidding based on royalty payments. The minimum area covered was 640 acres (259.2 ha), and the minimum royalty accepted was 12.5%. These royalties were to be divided among the **Reclamation** Fund (for western water projects), the states in which the land is located (for education and roads), and the federal government.

Amendments to the act have done away with prospecting permits, increased the size of tracts that can be leased, and changed the bidding procedures for leases. Most lands that are not known to contain oil are leased through a lottery conducted by the U. S. Department of the Interior. For known oil lands, a competitive bidding procedure is used. In addition to the bid fee, a 12.5% royalty and an annual rental fee of $2.00 per acre is also required.

The Mineral Leasing Act was a significant departure from past mining policy, based on the Mining Law of 1872, which granted free access to the public lands, the potential for inexpensive purchase of mineral lands, and included no royalty payments to the government.

Mining, undersea

Practically all of the mineral and energy resources found on land are present under the sea. Development, however, is limited by extraction costs that increase with depth of water, by the relative abundance of resources on land, and by political questions involving ownership of deep ocean resources.

Worth $80 billion, the most valuable undersea commodity is oil and **natural gas**, representing 90% of the resources obtained from the seafloor. Continental-margin deposits comprise about one-third of the world's estimated oil and gas reserves. Large deposits have been found on the continental shelves in the Gulf of Mexico, the Persian Gulf, the North Sea, and off the coasts of northern **Australia**, southern California, and the Arctic Ocean. Other sites are promising, and many other continental shelves remain relatively unexplored. The harsh conditions found in the North Sea have fostered huge investments in colossal offshore rigs. Extraction costs on the continental shelves are several times higher than on land, and projected costs in the Arctic Ocean are several times higher again. Such fields are profitable only because of their high flow rates and reserves. Oil exploration continues to push the limits of profitable extraction into deeper and deeper waters. One commercially promising well

in the Gulf of Mexico was drilled in waters well over 1 mi (1.6 km).

Nearshore resources are much more likely to be mined than distant ones. Sand and gravel predominate in volume. Though in great demand for use in concrete and as fill material and beach sand, their low value restricts usage to local areas.

Delta sediments are often mined for valuable deposits washed from the land, including gold, platinum, tin, diamonds, iron, and **uranium**. Japan, an island country with limited land resources, is especially eager to exploit such deposits; **coal** beds are also being mined.

Phosphorite is the source rock for phosphate, a key **fertilizer**. Phosphorite deposits occur where upwelling brings dissolved phosphate to the surface, where, in turn, rising temperature and **pH** cause them to precipitate out. Their value comes from their high grade, since they are not diluted by land-derived sediments.

Manganese nodules were first discovered on the deep-ocean floor during the 1873–76 voyage of the British ship, *Challenger*. Although rich in valuable ferroalloys used in steelmaking, these potato-like ores have yet to be mined commercially. The deposits are immense, but the technology for profitable mining does not currently exist.

Another tantalizing resource is the sulfide ores precipitated out of ocean water around **hydrothermal vents** in deep-ocean rift systems. Commercial extraction is being attempted in the Red Sea, and experimental vehicles have been built for use in the deep ocean, but technological and economic limitations hinder commercial development.

Economic considerations are one of the greatest limitations to the growth of undersea mining, along with uncertain environmental impact. Only highly profitable ventures, as in oil and gas extraction, or readily accessible, near-shore, bulk resources, such as sand and gravel, are currently feasible. Undersea mining appears to hold great potential **resources for the future**, when supplies and extraction costs of land-based resources tip the scales in its favor.

Political considerations, especially questions of ownership and the sharing of profits, are also key factors here, with developing countries clamoring for their share. During the 1970s, the United Nations strove for a treaty to regulate deep-ocean exploitation. The 1982 Law of the Sea Treaty claimed manganese nodules as the heritage of all humankind, to be regulated by the United Nations' seabed authority and with profits to be shared. The United States chose not to sign the treaty, and has joined with other developed countries in a provisional understanding to award exploitation licenses.

These political and environmental issues are insignificant, so long as the economic realities favor resources on land. It will be beneficial if the time spent waiting for development of undersea mining creates the opportunity for more productive international discussions and agreements.

Mirex

An organic compound that was manufactured for use as an insecticide against imported **fire ants** and, secondarily, as a fire retardant for **plastics**, **rubber**, paint, paper, and electrical products. It has a molecular weight of 545.59 and consists of twelve **chlorine** atoms attached to a ten **carbon** cage. Its full name is dodecachloro-octahydro-1,3,4-metheno-1H-cyclobuta[c,d]pentalene. The United States **Environmental Protection Agency** (EPA) has classified it as a **carcinogen**. Mirex can be degraded to the toxic **pesticide Kepone** in the **environment**. Due to discharges from manufacturing facilities in the state of New York, it is found in the water, sediments, and biota of Lake Ontario at levels of concern. *See also* Cancer; Great Lakes; Toxic substance

Mission to Planet Earth (NASA)

The Mission to Planet Earth (MTPE), now officially called the Earth Science Enterprise (ESE), is a program of the National Aeronautics and Space Administration (NASA) of the U.S. government. The mission is to use spacecraft and space technology to provide a comprehensive scientific study of the earth's living systems as viewed from space. Using satellites with precise measuring equipment, the mission will provide information about weather patterns, **climate**, oceans, coastlines, surface activity, atmospheric conditions, natural disasters, **pollution**, and hundreds of other measurements. The goals of the program, according to NASA, are to find out how the living system of the earth is changing, and to determine the causes and consequences of this change. NASA also has the goal of using the program's results to develop a "predictive capability" for climate, weather, and natural hazards. Finally, the program has an end-to-end strategy of performing studies and gathering data as well as making the findings readily available to the public and scientific community. Other countries are also taking part in the mission, including Canada, Japan, Russia,

and many major European countries, providing funding and scientific studies.

MTPE was initiated by President George Bush in 1989, on the recommendation of the **National Research Council**. At first, NASA and the U.S. government were ambitious about the plan to study the earth from space, and proposed a budget of $35 billion for its first 15 years. The original concept of the program was to build a huge observatory that would orbit and monitor the earth. The program was scaled down during budget battles in the early 1990s and received about $8 billion for its first decade of operation. The scientific concept of the program was changed as well due to the revised budget; MTPE will utilize up to 18 small satellites that will monitor the earth from space, called the Earth Observing System, and collect data that will be coordinated by computers. In 1998 NASA changed the name of MTPE to the Earth Science Enterprise.

By 2002, the program had several satellites and measuring instruments in space. The Earth Resources Observation System (EROS) has mapped cities and recorded urban growth and **habitat** destruction. The Geostationary Environmental Satellite (GOES) has tracked hurricanes and weather patterns. The Upper **Atmosphere** Research Satellite was launched in 1991 to study the **ozone** layer. In 1996 a Japanese satellite carried NASA instruments to study global wind patterns, and in 1997 a joint United States/Japanese satellite was launched to study how tropical rainfall affects the world's climate. In April 1999, NASA launched the Landsat 7 satellite to map and study environmental changes on the earth's surface, including mapping the world's forest canopy. In November 2000 a new generation of satellite was launched, the EO-1, which was only one-seventh the size of the Landsat satellites. The new satellite had sophisticated instruments, some of which can measure parameters such as the earth's gravity field. This measurement may help scientists better understand ocean currents and heat movement between the poles. Other governmental departments besides NASA are also contributing to the project. The National Oceanic and Atmospheric Administration's (NOAA) Polar-orbiting Operational Environmental Satellite is monitoring factors such as global vegetation, ocean currents, ice warming, weather patterns, the ozone layer, and solar storms. The MTPE was projected to consist of 25 measuring instruments on 10 satellites by 2002, depending on launch schedules and other factors.

NASA plans to make all of the data from MTPE satellites available to the public on computers. The information will be stored in NASA's Earth Observing System Data and Information System (EOSDIS). NASA estimates that MTPE satellites will send enough data back to Earth during its first 15 years of operation to fill nearly 6.5 million books per day. The management of this information will be as demanding a project as sending the satellites to space, and users will be able access the data from the Internet, CD-ROMs, tapes, microfiche, and photographs. By 2002 MTPE data was available via the Internet, including live broadcasts of the earth from satellites. Eventual users of MTPE data may include atmospheric scientists studying the ozone layer, meteorologists predicting weather changes, ecologists monitoring tropical rain forests, scholars performing environmental research, and many others interested in environmental patterns and problems.

Mixing zones

Most **wastewater** treatment plants and industrial facilities **discharge** their **effluent** into the nearest available body of surface water such as a stream or river. The mixing zone is the localized area in the receiving stream within which the mixing, dispersal, or dissipation of the effluent can be detected. For example, cooling water discharges from **power plants** typically create a mixing zone in the receiving stream where the temperature is higher than the ambient background temperature of the stream waters. Environmental regulations usually require that the mixing zone be limited in size and not create a nuisance or hazardous conditions.

Modeling (computer applications)

Computer modeling is a mathematical tool used to analyze complicated systems or to predict events such as floods, **climate** changes, or population changes. Computer models are applied in many disciplines, from engineering (predicting the strength of a bridge or dam) to economics (predicting inflation rates) to **ecology** (describing a **food chain/web** or projecting the survival chances of an **endangered species**). A model may consist of a few simple calculations on a spreadsheet, or it may involve millions of calculations on hundreds of thousands of input parameters, as in the case of general circulation models used to describe and predict climate conditions. Both simple and complex models involve quantifying input variables and the relationships between them, in order to produce numeric output that can describe or predict some real world phenomenon or condition. Models are often criticized because they can generalize real-world phenomena unrealistically, or because any errors in initial assumptions are expanded as assumptions are added and multiplied together. However, modeling remains a common tool because it is often the only available method to find answers to important research questions.

Models let researchers "experiment" with systems that do not allow manipulative experimentation. You cannot actually build a power plant just to test its effect on a population, and you cannot deliberately change the temperature of the **atmosphere** in order to see what happens to plant populations and sea levels. Instead a model can be used to predict probable outcomes of known conditions. Different variables can also be easily introduced in a model, for example, on the computer a programmer can easily add **pollution control** equipment to the power plant and observe its effect on lung disease rates in the surrounding population, or a modeler can easily reduce worldwide **carbon dioxide** emissions and calculate the impact on atmospheric temperatures.

Computer models have many applications. Some aid in assessing or visualizing a phenomenon. Three-dimensional geological models are used to help visualize or approximate the volume and dimensions of an **aquifer**, an oil reserve, or a magma chamber beneath a **volcano**. A simple **ecosystem** model can help identify general relationships between populations and resources, by letting the modeler adjust variables and see which arrangements most closely approximate observed data. Other models are used to predict the outcome of known conditions: a demographic model representing known rates of **population growth**, reproduction, and death can reasonably predict a country's population a century from now. Still other models are used to test "what if" questions. A **pollution** dispersion model showing how much pollution could spread from a power plant to a town can be used to test different scenarios: What if there were a northwest wind for an entire week? What if the power plant needed to double its energy production? What if the town expanded in the direction of the power plant? Models used to describe or visualize a system are known as descriptive models. Models that project or predict the results of input conditions are known as predictive models.

Anything that approximates or simulates a real-world phenomenon could be considered a model. A plaster replica of a landform, a diagram drawn on paper to describe links in a food web, or a verbal description of a storm could be considered models, because each of these describes or simulates a real phenomenon. Computer models approximate phenomena in the real world by performing calculations on input variables. These calculations produce numeric output that predicts the outcome of the variables in the model. For example, a wolf population model might multiply the number of breeding adults (A) by the average number of pups per litter (P) to produce the expected number of young **wolves** in a year (N): A x P= N.

This is a very simple, and not very realistic, mathematical model. A computer model can produce a more realistic representation of a wolf population, by incorporating more variables, by using randomized variables, by performing more complicated mathematical functions, and by repeating calculations many times in order to produce a statistically significant number of "experiments."

Models can be composed of variables, parameters, and constants. A variable is any factor that is changeable. The number of breeding adults in a wolf population might change from year to year, as might the number of pups per adult. Parameters are sometimes distinguished from variables as input factors that are unlikely to change: the number of litters in a wolf pack is unlikely to be more than one per year, or the month in which pups are born might reasonably be expected not to change from one year to the next. Constants are input factors that are assumed to be unchanging. In a model of a dam's structure and strength, the force of gravity on the water behind the dam would be a constant. In addition, randomized (stochastic), values can also be used to introduce an element of chance into the model. For example, in a simulation of population change in wolves a realistic birth rate may be somewhere between 4-9 pups per breeding female per year. A computer model can randomly select a number between 4-9, for this variable each time the model is run. In addition there might be a 70% chance that each pup would survive its first year. This stochastic variable could be added to increase the **precision** of the model's prediction of population at the end of the year. As the computer processes the model it arbitrarily picks a value for the stochastic variable. Stochastic variables can improve a model by making it better represent real events that are somewhat random, or at least unpredictable.

Deterministic and Stochastic Models

A deterministic model produces a single answer for each set of variables; that is, the input variables determine the outcome. Different results can be produced only by entering different values for the input variables. Deterministic models are useful where the values of input variables are reliably known. For example, if an engineer knows with reasonable certainty the strength of a concrete dam and the force applied by a full **reservoir**, a deterministic model should be used to calculate the water level that would cause the dam to break. A stochastic model, in contrast, includes an element of randomness, so that there will probably be a different result each time the model is run. For example, a population model might include a slightly randomized birth rate, or a reservoir model might include a randomized variable for rainfall, which in fact varies unpredictably from year to year. An advantage of using a stochastic (random) variable is that it helps the model approximate the fluctuations that can occur in a real system: there is no way to predict the actual number of pups a wolf pack will have each year, but it is possible to predict with some precision the minimum and maximum number that is likely. Running a stochastic model repeatedly can produce a statistically significant sample of experimental results. Statistical analysis can be used to assess the **probability** of various outcomes, such as a 25% probability that a wolf population will rise over the next 100 years.

Development of Modeling

Although mathematical models and analog models (physical structures such as clay models of landforms or **river basins**) have been used in environmental problem solving for a long time, the growth of modern computer modeling began in the 1960s with the development of computers. One of the first publicized computer models was a climate model that calculated climate conditions based on three input parameters: temperature, air pressure, and wind speed. Since then models have been used to predict weather, stream **discharge**, **soil erosion**, population growth, pollution impacts, and many other occurrences. The ability to use a computer greatly increased the complexity of models that could be developed, and the widespread availability of computers increased the number of people developing models for a growing number of purposes. Models are used in **environmental monitoring** and management, physics, engineering, **hydrology**, economics, demographics, and many other fields. One reason modeling developed more or less simultaneously in many disciplines is that the techniques of programming a computer to simulate real-world variables are highly portable: the structure of a model used to interpret water flow might be modified and applied to magma movement in the earth or to **nutrient** flows through a landscape. Modeling is now a widespread technique that is used to help explain how natural systems function and to inform public policy concerning the **environment**, the economy, and many other issues.

Sensitivity Analysis, Calibration, and Validation

Once a model is developed it is usually tested against observed events or data to indicate how reliable it is or where its weaknesses lie. One of the first tests usually run is sensitivity analysis. A model's outcome may be more sensitive to changes in one variable or process than another: in a beach erosion model, for example, the predicted erosion rate is likely to be influenced more by wave energy than by sand particle size, even though both factors need to be considered. It is essential to know to which factors the model is most sensitive, because error in estimating those factors could introduce significant error into the results. Sensitivity analysis involves adjusting variables or processes and then running the model to see which factors cause the greatest variability in outcomes.

Once the input variables and relationships in a model are established, the model can be calibrated, or tuned, to make it better represent reality. Calibration usually entails adjusting different parameters in order to produce a result similar to some observed results in the real world. Calibrating a model for forest growth, for example, might involve running the model repeatedly with different growth rates until the model approximates observed historic growth rates and densities.

Validation is like calibration, in that it involves comparing a model's results to observed data. The objective of validation, though, is to demonstrate that the model is reliable. The assumption of model validation is that if the model predicts the correct results in a known situation, then it will probably predict correctly in an unknown, experimental situation.

General Circulation Models

A type of model that has received much attention since the mid-1980s is the general circulation model, or GCM. This is a class of highly complex models designed to predict with reasonable **accuracy** the behavior of the earth's atmosphere (climate) or oceans. GCMs have been used to predict worldwide global warming as a result of increased concentrations of **carbon** dioxide in the atmosphere. GCMs are complex because they simulate the behavior of the atmosphere and the oceans, which have complex three-dimensional movements or flows of air masses or water. Predicting how changes in heat input at one location impacts temperatures and flow rates at another location requires thousands of calculations performed on many interrelated variables at thousands of points in space. Because GCMs must keep track of so many variables and so many points in space, they are usually run on supercomputers that can perform (billions) of calculations per second.

The appropriate complexity of a model depends on its intended use. A model designed to describe ocean circulation over space and time to produce realistic results on which to base public policy might incorporate many variables. A model built to test very general relationships between variables, in order to stimulate a researcher's insight into a small aspect of ecosystem functions, may more appropriately be quite simple, with only a few input parameters and equations.

Dr. Mario Jose Molina (1943 –)

Mexican chemist

Mario Molina was born on March 19, 1943, in Mexico. He received his bachelor's degree from the National Autonomous University of Mexico in 1965 and his Ph.D. in physical chemistry from the University of California at Berkeley in 1972. After teaching for a year at the National Autonomous University, he returned to Berkeley as a research associate for one year.

In 1973, Molina joined the research laboratory of F. Sherwood Rowland at the University of California at Irvine. Molina was looking for a topic on which he could do his post-doctoral research with Rowland, and Rowland was ready with a suggestion because he had just come from a scientific meeting where he became interested in the possible effects of an important commercial chemical, trichlorofluoromethane, also known as chlorofluorocarbon-11, or CFC-11. The compound was a member of a widely-successful group of **chemicals**, called freons, produced by Dow Chemical Company.

In particular, the question that interested Rowland was what effects, if any, this compound would have on atmospheric gases. CFC-11 was rapidly becoming very popular as a propellant in hair sprays, spray paints, and other **aerosol** products. By 1974, more than $2 billion of CFC-11 and related **chlorofluorocarbons** were being used each year.

Rowland and Molina developed a theory about the fate of CFC molecules released in the **troposphere**, the layer of the **atmosphere** in which we live. They predicted that those molecules would rise into the **stratosphere**, the layer of air above the troposphere. There, they said, **solar energy** would cause CFC molecules to decompose, releasing free **chlorine** atoms.

If that were to happen, they hypothesized, the free chlorine would be likely to attack **ozone** molecules, converting them to ordinary oxygen. The chlorine oxide formed in that reaction might then react with single oxygen atoms, to form more oxygen and regenerate the original chlorine.

Two important conclusions can be drawn from this series of reactions. First, a single atom of chlorine would be capable of destroying many (Rowland and Molina predicted about 100,000) molecules of ozone. Second, since ozone in the stratosphere absorbs **ultraviolet radiation**, this process would result in more ultraviolet radiation reaching the earth's surface and causing an increase of skin **cancer** among humans.

When Rowland and Molina first proposed this theory, no measurements had ever been made of chlorine in the stratosphere. By 1979, they had carried out the first of those measurements and obtained results that closely matched their predictions. An important new environmental problem, **ozone layer depletion**, had been identified.

Molina held positions as a research associate, assistant professor, and associate professor at the University of California at Irvine. In 1983, he left Irvine to become Senior Research Scientist at the Jet Propulsion Laboratory at the California Institute of Technology in Pasadena. Molina was awarded the Society of Hispanic Engineers Award in 1983. He is also the recipient of more than a dozen awards including the 1987 American Chemical Society Esselen Award, the 1988 American Association for the Advancement of Science Newcomb-Cleveland Prize, the 1989 NASA Medal for Exceptional Scientific Advancement, and the 1989 United Nations Environmental Programme Global 500 Award. In 1995, he received the Nobel Prize in Chemistry along with F. S. Rowland and P. Crutzen.

Monarch butterfly

Like all butterflies, moths, and other insects with a lifecycle that involves complete metamorphosis, individual monarch butterflies (*Danaus plexippus*) go through four stages from eggs to larvae (caterpillars) to pupae to adults. Unlike other insects, as a **species** monarchs also undergo an annual cycle that involves several generations and a **migration** that covers thousands of miles.

Monarch butterflies are native to North and South America, but have were spread by humans throughout much of the world in the 1800s. They first appeared in Hawaii in the 1840s, then spread throughout the rest of the South Pacific in the 1850s and 1860s. In the early 1870s, the first monarchs were reported in **Australia** and New Zealand. These different populations have adapted to their new habitats with an amazing range of behaviors, but the annual migration undergone by the North American monarchs makes them unique among insects.

It is thought that there are three distinct populations of monarchs in the United States. One breeds east of the Rocky Mountains and overwinters in the mountains of central Mexico. Another breeds west of the Rocky Mountains and overwinters on the California coast. These populations constitute separate breeding pools with little genetic exchange. A third population is found in southern Florida. This population is genetically less isolated and probably receives significant influx from the eastern population in the fall and possibly the spring.

The monarch life cycle

An individual monarch's life cycle begins when a female lays an egg on a plant in the milkweed family (Asclepiadacae). Dozens of milkweed species are found throughout North America, and most of these are suitable hosts for monarchs. Common milkweed (*Asclepias syriaca*) in the northern United States and Canada, is probably host to more monarchs than any other species. It is difficult to tell just how many eggs each butterfly lays during her life, but the average female in the wild is thought to lay 300–500 eggs. In captive females average about 700 eggs over two to five weeks of egg laying. Eggs usually hatch three to seven days after they are laid.

The newly hatched larva's first food is its egg-casing, but it soon begins eating the plant on which it was hatched. Only after consuming milkweed does the larva develop the characteristic yellow, white, and black striped pattern recognized by children and adults throughout the world. Monarch larvae undergo five stages called instars, shedding their old skin between stages to allow for growth. The main activity of the larva is eating, and during the larval period of about eight to 14 days, they increase their mass about 2,000-fold.

The third stage in the monarch life cycle is the pupa, or chrysalis. When the monarch is ready to pupate, it seeks a protected location and spins a white silk pad using a spinneret located just under its mouth. It attaches itself to this pad and dangles head down. About a day later it sheds its skin for the last time and the gold-spotted green chrysalis, or pupa, is complete. This stage lasts eight to 15 days. The day before the adult butterfly emerges, its folded wings are visible through the pupa case, and it is possible to see the black, orange and white color pattern that is the monarch's trademark. This pattern is due to tiny scales that cover the monarch's wings and body. On the day that the butterfly emerges, the colors are very distinct and the pupa no longer has any green coloring.

Adults live for two to six weeks, spending their time gathering nectar from flowers, mating, and laying eggs. Four to five generations repeat this cycle throughout the spring and summer.

The monarch's annual cycle

Butterflies that emerge in late August and September put reproduction on hold. Instead of eating, mating, and laying eggs, the adults fly south. Individuals in the eastern North American population, live up to nine times as long as their spring and summer counterparts. They travel to old growth oyamel fir (*Abies religiosa*) forests high in the transvolcanic mountains of Michoacan, Mexico. West coast monarchs also begin a migration that will end in the eucalyptus and Monterey pine (*Pinus radiata*)groves of Pacific Grove, Santa Cruz, and Fremont on the Central California coast.

Starting in early November, the monarchs form compact roosts thickly covering the trunks and branches of hundreds of trees. They remain in a nearly dormant state until the temperatures warm in February, when they become more active, mating, and seeking water and nectar. In mid-March, they fly north to look for the milkweed plants in order to produce new generations of monarchs that will continue the migration cycle. Recolonization of the summer breeding grounds is a two-step process. Monarchs that have overwintered make part of the return trip. Then they lay eggs and die. Their offspring continue the journey north until the breeding range is reoccupied by late May or early June.

Because of their incredible yearly migration cycle, monarchs depend on resources in widely dispersed locations, making them especially vulnerable to disruption of their **habitat**. In their breeding range throughout the United States and southern Canada, they need fields, roadsides, gardens, and prairies filled with milkweed for larvae and nectar sources for adults. During their fall migration monarchs need safe flyways and nectar sources to fuel their long journey. Finally, the migratory generation requires an intact habitat in their wintering one that will protect them from

temperature and humidity extremes during their winter rest. Just as with migratory song birds, preserving the monarch's migratory life cycle requires international interest, knowledge, and cooperation.

Monarch population size

There are no reliable estimates of monarch population size during the breeding stage of the annual cycle. However, estimates of absolute numbers during the overwintering period exist. During the winters of 1985 to 2002, researchers estimated that overwintering monarch densities are approximately 10 million butterflies per hectare, with 6–12 hectares of land used for roosting. However, estimates of monarch **mortality** during a major winter storm in 2002 suggested that this estimate is too low, and that densities may be more like 50 or 60 million monarchs per hectare of occupied forest.

Sources of monarch mortality

About 90–95% of monarch eggs never reach adulthood, and predators, milkweed defenses, and environmental conditions can all cause mortality during the immature stages. Predators and environmental conditions can also kill adults. Habitat destruction limits the number of monarchs reaching maturity during the summer breeding period, and also affects the number that survive the overwintering period.

Invertebrate predators such as insects and spiders, and diseases caused by bacteria, viruses, **fungi**, and other organisms kill many monarchs in natural populations. Invertebrate predators of monarchs include both native and introduced flies and wasps that lay eggs in living larvae or on the leaves that larvae eat. The wasp or fly larvae that emerge from these eggs ultimately kill the monarch larvae.

Monarchs accumulate **chemicals** called cardenolides (also called cardiac glycosides) that are present in the milkweed. These cardenolides are poisonous to most vertebrates, and monarchs face little predation from **frogs**, lizards, mice, or birds during the adult breeding stage. However, vertebrate predation is a major source of mortality for overwintering monarchs. Both birds and mice consume significant numbers of overwintering adults.

The milky latex present in milkweed leaves is contained under pressure in a system of vesicles. When the plant is punctured, the latex flows out of these vesicles and coagulates on contact with air. The latex serves as a defense to the plant, since it is similar to glue after coagulation. It can kill small larvae by sealing their mandibles or gluing their entire body to the leaf. While monarch larvae can cut off latex flow by trenching the leaves, about 25% of first instar larvae die after becoming mired in the latex of some milkweed species.

Monarch eggs do not hatch in very dry conditions. Dry weather can also reduce the population of monarch by killing milkweed and reducing the amount of nectar in flowers. Very hot weather also causes mortality. Studies have shown that prolonged temperatures above approximately 95°F (35°C) can be lethal to all stages. Likewise, temperatures below freezing can kill monarchs. All stages can survive if temperatures are only a few degrees below freezing for short periods, but extended periods of severe cold and wet kill them. In the overwintering colonies, the highest mortality occurs when adult monarchs become wet from rain or snowfall, then are subjected to freezing temperatures. Since temperatures extremes are likely to be greater in forests that have been thinned, **logging** can exacerbate the effects of winter storms.

The most important source of human-caused mortality in the breeding range of monarch is habitat loss, especially the destruction of milkweed and nectar sources. Milkweed is considered a noxious weed by some people, and is often destroyed. Herbicides used in agriculture and on roadsides and lawns kill both nectar plants needed by adults and milkweed needed by larvae. Monarchs are also exposed to insecticides used to control insects such as mosquitoes. Research conducted in 2001 found that most monarchs in the upper Midwest probably originate in agricultural fields, especially corn and soybean fields. This means that any agricultural practices that affect milkweed abundance or monarch survival in these fields could have large impacts on monarch populations.

There is also concern that genetically corn containing Bt toxin is a hazard to monarchs. Pollen produced by this corn contains the toxin. Pollen may be blown onto milkweed plants growing in and near cornfields. Since many monarchs that migrate to Mexico breed in the corn belt of the central United States, and milkweed growing within cornfields constitutes an important food source for these monarchs, exposure to this risk is likely to be high. The most commonly used Bt strains express levels of toxin in their pollen that are unlikely to kill monarch larvae outright. Sublethal impacts have not been closely studied.

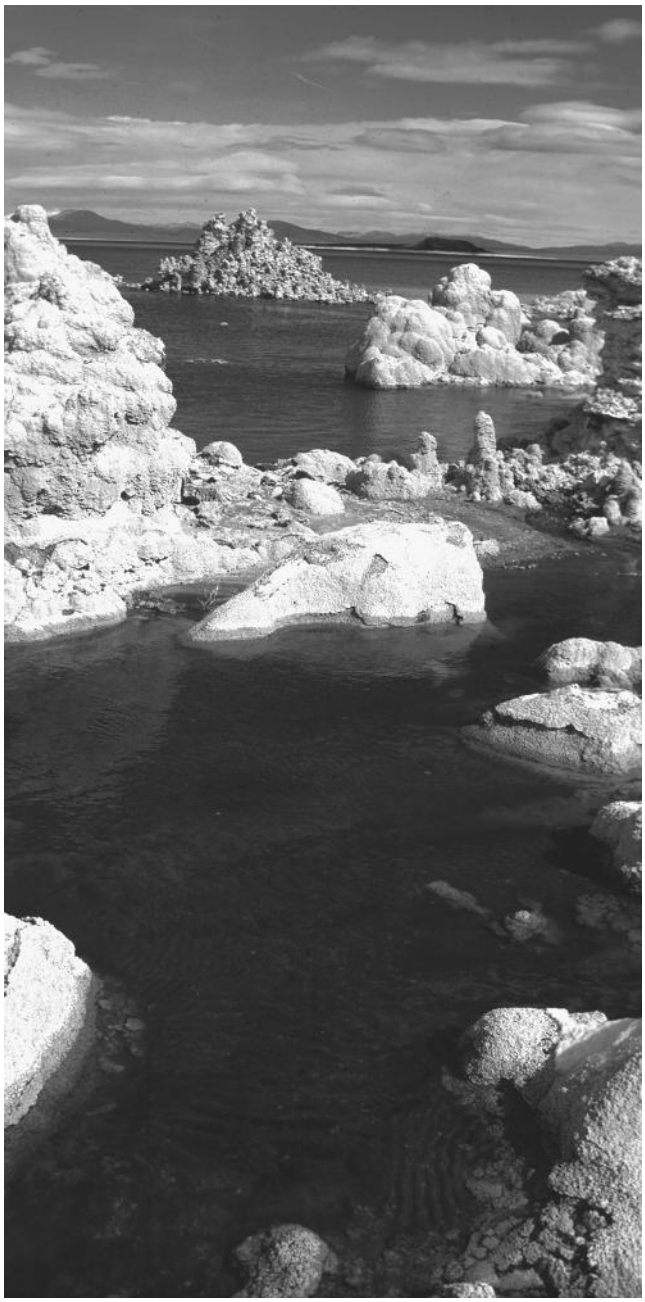
Monkey-wrenching

Also called *ecotage* (ecological sabotage), monkey-wrenching refers to techniques used by some radical environmentalists to stop or slow the machinery used in **logging**, **strip mining**, and other sorts of environmentally destructive activities. The term was popularized by Edward Abbey's novel, *The Monkey Wrench Gang* (1975) and the concept was developed by **Dave Foreman** in *Ecodefense: A Field Guide to Monkeywrenching* (1987). The techniques of monkey-wrenching include "spiking" old-growth trees to prevent loggers from cutting them down, "munching" logging roads with nails to puncture the tires of logging vehicles, pulling up surveyors' stakes, putting sand or grinding compound in the gas tanks or oil intakes (or oatmeal or Minute Rice in the radiators) of bulldozers and logging trucks, and other forms of disruption or destruction.

Mono Lake

Clear, cold water tumbles from snowcapped peaks and alpine fields at 13,000 ft (4,000 m) down the precipitous eastern escarpment of California's Sierra Nevada. The water feeds semi-arid, sagebrush–covered Mono Basin and, at the basin's heart, majestic Mono Lake. This is a salt lake with an area of 60 square miles (155 km^2) at an elevation of 6,400 ft (2,000 m), and mountain waters have flowed to it for at least the past half million years, making it one of the oldest lakes in North America.



Mono Basin lies in the **rain shadow** of the Sierra Nevada; shielded from moist Pacific air masses to the west, it has a semi-arid **climate**. Being surrounded by higher ground, it also has no natural outlet. Over the millennia, the major water loss from Mono Lake has been by evaporation, a process that removes pure water and leaves dissolved salts behind, and the water in the lake has become alkaline as a result and two and a half times saltier than sea water.

The salty, alkaline lake water excludes fish, but it does provide ideal conditions for several life forms that normally are uncommon to inland waters. Algae blooms in abundance during winter, sometimes turning the lake water pea–soup green, and it provides summer sustenance to a profusion of brine flies and tiny brine shrimp. Brine flies and brine shrimp make Mono Lake a summer haven for hundreds of thousands of nesting and migratory birds. The lake's islands provide safe nesting for tens of thousands of California gulls and snowy plovers. Nearly 90% of the state's population of California gulls, which live mainly along the Pacific coast, are hatched on these islands. More than 70 **species** of migratory birds use Mono Lake—most notably, several hundred thousand eared grebes which stop over during their fall **migration**, and more than 100,000 phalaropes which come from South America for the summer.

Mono Lake's **aquatic chemistry**, combined with its unusual geologic and topographic **environment**, has given rise to the lake's signature feature: tufa towers. Tufa is a type of limestone which consists of calcium carbonate that forms around fresh water springs emanating from the lake bottom. Calcium carried by the spring water combines with carbonate in the alkaline lake to form soft rock masses that slowly grow into underwater pinnacles. These towers were almost entirely covered by water until recently; they were first exposed when the lake level started dropping in the early 1940s, because the growing city of Los Angeles had begun intercepting fresh water from streams feeding the lake and diverting it south to the city in a 250–mi (400 km) long aqueduct.

By the mid-1980s, Mono Basin supplied nearly 20% of the water used by Los Angeles, and the lake level had dropped more than 40 ft (12 m). As the water level dropped, the lake's **salinity** increased and shoreline **habitat** for brine flies decreased. Tufa formations became more exposed, dust storms grew more frequent and severe, and predators occasionally found access to island nesting sites. Meanwhile, California created the Mono Lake Tufa State Reserve, and

A view of frost covered rocks in Mono Lake, California. (Photograph by R. Rowan. Photo Researchers Inc. Reproduced by permission.)

the United States Congress established the Mono Basin **National Forest** Scenic Area.

Ultimately, the demand for water by Los Angeles clashed with the demands of environmental groups, who sought to maintain Mono Lake's **ecological integrity** and the fish habitat of streams feeding the lake. Lawsuits have been fought in state and federal courts, and in 1989 California's State Supreme Court ordered the Los Angeles Department of Water and Power (LADWP) to reduce the amount of water it was diverting from the lake. In 1993, the State **Water Resources** Control Board recommended that the diversion be cut again, this time by half. LADWP has disagreed, arguing that Los Angeles needs the water and that the reduction is neither ecologically necessary nor economically wise.

The war over eastern Sierra water began at the turn of the twentieth century, when Los Angeles acquired rights to water previously used by farmers and ranchers in the Owens Valley, just south of Mono Lake. By mid–century the battleground had spread north to Mono Basin, and the war promises to continue well into the next century. *See also* Drinking-water supply; Hydrologic cycle; Los Angeles Basin; National forest; Water allocation; Water resources; Water rights

Monoculture

The agricultural practice of planting only one or two crops over large areas. In the United States, corn and soybean are the only crops grown on most farms in the central Midwest, while on the Great Plains wheat is almost exclusively grown. Although it minimizes farmers' investments in large, expensive implements, the practice exposes crops to the risk of being wiped out by a single predator. This happened with the Irish potato blight of the 1840s and the corn leaf blight of 1970 in the United States, which destroyed millions of acres of corn. Ecologists warn against monoculture's oversimplification of the **food chain/web**, arguing that complex webs are more stable.

Monsoon

Monsoon (from Arabic, *mausim*, season) technically means a reversal of winds, that point between the dry and the wet seasons in tropical and subtropical India, Southeast Asia, and parts of Africa and **Australia**, when seasonal winds change their direction. When the land heats up, the hot air

Each summer, warming air rises over the plains of central India, creating a low-pressure cell that draws in warm, moisture-laden air from the ocean. Rising over the Western Ghats or the Himalayas, the air cools causing heavy monsoon rains. (McGraw-Hill Inc. Reproduced by permission.)

rises, causing a low pressure zone that sucks in moisture-filled cooler ocean air, creating clouds and producing rain. In winter, the opposite happens: warm air over the ocean rises and makes a low pressure zone that draws the cooler air off the land.

Although monsoon winds have always been watched by traders and sailors in the Eastern Hemisphere, their arrival is critical to millions of people who depend on agriculture. Cultural and religious customs, especially in India and southeast Asia, are tied to the monsoon rains that bring a season of fertility after a long hot and sterile dry period.

Coastal radar and satellites aid in weather prediction, but the climatological components of monsoons are complex. Tied to the heat and moisture exchange between land and oceans, their effect can be altered by changes in the circulation of hemispheric winds at the equator, as well as by precessional changes in the orbit of the earth.

Environmental changes such as **deforestation** or **soil erosion** can invite severe **flooding**, as in Bangladesh during the 1980s. Scientists believe a rise in sea surface temperature in the Atlantic Ocean, possibly related to the **greenhouse effect**, prevented the monsoon rain from reaching the African **Sahel** and contributed to recent droughts. This ocean temperature rise may also be tied to the **El Niño** event in the Pacific Ocean.

Any fluctuations in monsoon rain patterns can cause disease and death, along with millions of dollars in damage. If the rains are delayed, or never come, or fall too heavily in the beginning or at the end of the growing season, disastrous results often follow. *See also* Climate; Cloud chemistry; Meteorology

Montreal Protocol on Substances That Deplete the Ozone Layer (1987)

A historical agreement made in 1987 by members of the United Nations to phase out substances that are harmful to the earth's **ozone** layer. The ozone layer protects life on earth by blocking out the sun's harmful **ultraviolet radiation**. Since the 1970s scientists have documented the depletion of the ozone by **chlorofluorocarbons** (CFCs), commonly used for refrigeration and as solvents and **aerosol propellants**. Alarmed by this growing global trend, scientists and policymakers urged a decrease in the use and production of CFCs as well as other ozone-damaging **chemicals**. Ratifying the 1987 Montreal Protocol was a difficult process, however, with the European Community, the former Soviet Union, and Japan reluctant to pose strict controls on chemicals reduction. United States, Canada, Norway, and Sweden, among others, favored stronger control and negotiated with these nations to cut back and eventually phase out completely ozone-depleting substances.

An amendment of the Montreal Protocol was made in 1990 by 93 nations, including China and India, who had not previously participated, to eliminate the use of CFCs, **carbon** tetrachloride, and halon gases by the year 2000 and eliminate the production of methyl chloroform by 2005. Some countries, like the United States, accelerated the schedule to 1995. This 1990 amendment also established the "Montreal Protocol Multilateral Fund" to help developing countries become less dependent on ozone-depleting chemicals.

In November 1992 delegates from all over the world met again in Copenhagen, Denmark, to further revise the Montreal Protocol and accelerate the phase-out of ozone-damaging substances and regulate three additional chemicals. Some of those provisions were as follows: phase out production of CFCs and carbon tetrachloride by 1996; ban **halons** by 1994 (the production of halogen was ended in 1994 in most industrialized nations and is expected to be halted in China, Korea, India, and the former Soviet Union by 2010); end production of methyl chloroform by 1996;

control the use of hydrochloroflurocarbons (HCFCs) and eliminate them by 2030; and increase funding for the Multilateral Fund (between $340 and $500 million by 1996).

Since the Copenhagen Amendments there have been other amendments, such as the Montreal Amendment of 1997, which according to the *Journal of Environmental Law & Policy* "adjusted the timetable for phaseout of some substances and modified trade restrictions, including the creation of a licensing system to attempt to decrease the black market in ozone depleting substances;" and the Beijing Amendment in 2002, which closely monitors bromochloromethane and the trade of hydrochloroflurocarbons.

As of July 2002, 175 nations have ratified the Montreal Protocol. However, while countries have volunteered to control ozone-damaging chemicals, individual companies can still produce the banned chemicals for "essential uses and for servicing certain existing equipment." The Alliance for Responsible CFC Policy in Arlington, Vermont, praised the concession for balancing environmental and economic concerns. Others, such as members of the **Friends of the Earth**, decry the provision as a "big loophole" that undermines the initiative of the Montreal Protocol. *See also* Ozone layer depletion

More developed country

The terms more developed countries (MDCs) and **less developed countries** (LDC) were coined by economists to classify the world's 183 countries on the basis of economic development (average annual per capita income and gross national product). The 33 countries (including the United States, Canada, Japan, **Australia**, New Zealand and all the western European countries) in the MDC group are wealthy and industrially-developed. They tend to have temperate climates and fertile soils. About 23 percent of the world's population live in MDCs, but they consume about 80 percent of its mineral and energy resources. In contrast the LDCs are poorer and less industrially-developed. They tend to be located in the Southern Hemisphere where the **climate** is less favorable and soils are generally less fertile. Though the boundaries are purposely vague, this dichotomy is useful for contrasting the economic and social welfare of the richer and poorer countries and in critical environmental categories involving mainly demographic, economic, and social **statistics**. *See also* Environmental economics; First World; Third World

Mortality

A measure of the death rate in a biological population, usually presented in terms of the number of deaths per hundred or per thousand. If there are 100 mice at the beginning of the year and fifteen of them die by the end of the year, the group's mortality rate is fifteen per 100 individuals (the initial population), or 15 percent. In ecological and demographic studies of populations mortality is an important measurement, along with birth rates (natality), immigration, and emigration, used to assess changes in population size over time. In human populations mortality rates are often figured for specific age and gender groups, or for other population categories including race, income level, occupation, and so on. This way group mortality rates can be compared and risks for each subgroup can be evaluated. *See also* Evolution; Extinction; Population growth; Zero population growth

Mount Pinatubo

Mount Pinatubo in the Philippines erupted on June 15, 1991. When the 5,770-ft (1760 m) mountain shot **sulfur dioxide** 25 mi (40 km) into the **atmosphere**, the cloud mixed with water vapor and circled the globe in 21 days, temporarily offsetting the effects of global warming. Satellite images taken of the area after the eruption showed a dustlike smudge in the **stratosphere**. The sulfur dioxide cloud deflected 2% of the earth's incoming sunlight and lowered temperatures on worldwide average. Although the effects on global temperatures were significant, they are thought to be temporary. These light sulfur dioxides are expected to remain in the stratosphere for years and contribute to damage to the **ozone** layer.

The Philippine islands originated as volcanoes built up from the ocean floor. Most volcanoes erupt along plate edges where ocean floors plunge under continents and melting rock rises to the surface as magma. The earth's crust pulls apart, creating gaps where the magma can rise. The island of Luzon, where Mount Pinatubo is located, has thirteen active volcanoes. The pattern of volcanoes around the rim of the Pacific Ocean is called the Ring of Fire.

Mount Pinatubo sits in the center of a 3-mi (5-km) wide *caldera*, a depression from an earlier eruption that made the **volcano** collapse in on itself. A new cone formed over time, and geothermal vents gave a clue that the volcano was active. Before the 1991 eruption, Mount Pinatubo last erupted 600 years ago. In April 1991 steam eruptions, earthquakes, increasing sulfur dioxide emissions, and rapid growth of a lava dome all indicated a powerful impending blast. Minor explosions began on the mountain on June 12, 1991.

This major eruption occurred in a country with an already shaky economy, and the human effects are likely to be significant for a long period of time. A total of 42,000 homes and 100,000 acres (40,500 ha) of crops were destroyed. Nine hundred people died and 200,000 were relocated, with 20,000 people remaining in tent cities. More than 500 of those have died from disease and exposure. The country suffered over $1 billion in economic losses. Nevertheless, many lives were saved as a consequence of scientists' predictions of the eruption.

The destruction from Mount Pinatubo came mostly from lahars, rushs of cementlike mud, formed when heavy rains loosened the tons of ash dumped on the mountain's sides. These lahars can bury towns and roads and virtually anything else in the way. Also deadly were the pyroclastic flows, killer clouds of hot gases, pumice, and ash that traveled up to 80 mi (130 km) per hour across the countryside, up to 11 mi (18 km) away from the volcano. *See also* Geothermal energy; Greenhouse effect; Ozone layer depletion; Plate tectonics

Mount St. Helens

On May 18, 1980, Mount St. Helens exploded with a force comparable to 500 Hiroshima-sized atom bombs. David Johnston, a United States **Geological Survey** (USGS) geologist based at a monitoring station six miles (9.7 km) away announced the eruption with his final words, "Vancouver, Vancouver, this is it." Dramatic photograph's provided the public with an awesome display of nature's power.

Mount St. Helens, in southwestern Washington near Portland, Oregon, is part of the Cascade Range, a chain of subduction volcanoes running from northern California through Washington. The Mount St. Helens eruption was instrumental in the expansion of the USGS **Volcano** Hazards Program. Research at the new Cascades Volcano Observatory in Vancouver, Washington, has strengthened basic understanding of volcanic processes and the ability to predict eruptions. Highly relevant ecological studies have corrected previous errors and misconceptions, leading to a new theory about nature's ability to recover after such events.

Research has heightened public awareness of the inherent instability of high, snow-covered volcanoes, where even small eruptions can almost instantaneously melt large volumes of snow. A relatively small 1985 eruption at Nevado del Ruiz in central Colombia killed more than 23,000 people. The Mount St. Helens blast and subsequent collapse generated a 0.7 cubic mile (2.8 km^3) mud flow which raced 22 miles (35 km) at speeds as high as 157 mph (253 kph). This caused massive problems, even halting traffic on the Columbia River. These flows may also create unstable **dams**, which may burst years after the intial eruption.

In addition to its awesome power and destructive force, the Mount St. Helens eruption has provided rich material for research. Conductivity studies have located a large rotating block under Mounts Rainier, Adams, and St. Helens, the friction from which is a likely source of eruptions. Geologic mapping and historical research, coupled with field studies of current volcanism, have corrected misconceptions and given clues to hazard frequency. Studies of nature's recovery efforts have produced surprises, notably the early arrival in the eruption zone of predatory insects; elk grazing in open, reforested areas; and the explosive growth of uncommon, dangerous bacteria due to the high temperatures generated by the eruption. *Biological legacy* has emerged as the unifying theory describing nature's recovery capabilities, an idea with direct applications to forestry practices and **reclamation** of human-disturbed land. Nature's mess provides valuable nutrients and nurseries; furthermore, old growth areas within managed ecosystems nurture the recovery of **biodiversity**.

Mount St. Helens has provided a unique laboratory for study of volcano hazards and nature's ability to recover

Mount St. Helens erupting with Mt. Hood in the background. (UPI/Corbis-Bettmann Newsphotos. Reproduced by permission.)

from the devastation caused by volcanic eruptions. *See also* Mount Pinatubo, Philippines; Reclamation; Topography

John Muir (1838 – 1914)

American naturalist and writer

John Muir is considered one of the towering giants of the conservation/environmental movement in the United States. Anyone seriously interested in natural history, **conservation**, **wilderness** preservation, or the national parks in this country should be aware of John Muir's work. He was a spirited, joyous naturalist, a serious student of glaciers, an influential advocate of wilderness preservation, and the acknowledged founder of the **national park** idea. Born in Dunbar, Scotland, Muir emigrated with his family to the United States in 1849 when he was 11 years old. He spent his youth working on a farm in the Wisconsin wilderness, trying to please his father, who was a deeply religious man. The wilderness, his religious background, and the hard labor influenced his thinking the rest of his life.

Muir's father believed the Bible to be the only book necessary for a young person, but Muir managed to educate himself and to spend several years at the University of Wisconsin (where he chose his own curriculum and so left without a degree). After school, he worked at various jobs, gener-

ally quite successfully, until a factory accident temporarily blinded him. He vowed that if his sight returned, he would leave the factory and see as much of the world as possible. After about a month, his sight did return and he left for various jaunts in the wilderness, including a famous 1,000-mi (1,609 km) walk through the country to the Gulf of Mexico, an account recorded in *A Thousand Mile Walk to the Gulf* (1916).

His eventual goal was to reach South America and wander through the Amazonian tropical rain forests. He reached Cuba, but a bout with fever (carried over from the humid lowlands of Florida) turned him instead toward the drier West, especially California and the Yosemite Valley, about which he had seen a brochure and which he determined to see for himself. "Seeing for himself" also became a life-time habit, and he eventually traveled over much of the world. As he had planned, he did make it up the Amazon, in 1911, at the age of 73.

Arriving in California in 1868, he made his way to Yosemite and spent several years studying its landforms, **wildlife**, and waterways, earning his living by herding sheep, working in a sawmill, and other odd jobs. As Edward Hoagland noted, Muir "lived to hike," a mode of **transportation** that involved him intimately in the landscape. He traveled light, and alone, often with little more than some dry bread in a sack, tea in a pocket, a few matches and a tin cup, and perhaps a plant press.

Through his travels in Yosemite, he became convinced that the spectacular land forms of Yosemite had been carved by glaciers or, as he put it, "nature chose for a tool...the tender snow-flowers noiselessly falling through unnumbered centuries." His belief in glacial origins placed him in conflict with the established scientific ideas of the time, especially those held by the California state geologist. But Muir eventually prevailed, his ideas vindicated when he found the first known glacier in the Sierra range. The results of his years of intense glacial investigations are available in *Studies in the Sierra* (1950). Current views have verified his theories, changing only the number of glacial events and emphasizing the role of water in cutting the canyons. Muir also made five trips to Alaska to study glaciers there, one of which is named for him.

His glacial studies were the principle contributions Muir made as an original scientist, most of his life being devoted to travel, writing, and conservation activism. Even as early as 1868, Muir was concerned with the effects sheepherding had on plant life and **soil erosion**.

Muir's travels were interrupted for a time when, in early 1880, he married Louise Strentzel, the daughter of a fruit rancher in the Alhambra valley. Muir helped run the ranch, first rented and then bought some of the acreage, applying his inventiveness and hard work to fruit growing. Reportedly, he was a good businessman, prospering after only a decade to ensure a measure of financial independence. He then sold part of the ranch and leased the rest, which allowed him time with his daughters, to return to his beloved wilderness, and to write and actively promote his wilderness ideas. Muir's intimate acquaintance with the Yosemite area and the Sierra Nevada exposed him not only to the depredations of sheep but also to the rapid felling of giant old Sequoias, cut up for shingles and grape stakes. Muir's response: "As well sell the rain clouds, and the snow, and the river, to be cut up and carried away...." In 1889, he escorted the editor of *Century* magazine to Yosemite and showed him the negative impacts of sheep, which he called "hoofed locusts." A series of articles in that magazine alerted the public to the destruction of the land, and they eventually pressured Congress to establish the Yosemite area a national park in 1890.

An earlier attempt to rally interest in the plight of the western forests—a suggestion for a government commission to survey the forests and recommend conservation measures—was also realized with the appointment of such a commission in 1896. Charles Sargent, the chair of the commission, invited Muir to participate and, on the basis of the Sargent Commission's recommendation, President Grover Cleveland created thirteen forest preserves, setting aside 21 million acres. Negative reaction from commercial interests, however, nullified most of these gains. Muir responded by writing two articles on forest reserves and parks in *Harper's Weekly* and *Atlantic Monthly* in 1897. These articles helped to rally public support and in 1898, the annulments were reversed by Congress.

Muir influenced the public and extended his influence by friendships and correspondence with some of the most powerful people of his time. A number of the successes of the early conservation movement, for example, can be attributed to his influence on such figures as **Theodore Roosevelt**. After a three-day camping trip with Muir under the Big Trees in 1903, Roosevelt added many millions more acres to the **national forest** system, as well as national monuments and national parks and created what became the **national wildlife refuge** system.

Known for his many successes, Muir was much saddened by his one big loss: the damming of Hetch Hetchy valley in **Yosemite National Park** as a **reservoir** to supply water to San Francisco. Muir's public image was damaged by the excessive vehemence of his attacks upon the citizens of San Francisco, whom he denounced as "satanic," and following the Hetch Hetchy incident, Muir retired to his ranch to edit his journals for publication.

Muir never considered himself much of a writer and begrudged the time it took away from his beloved mountains and forests. Most of his books were published late in life,

John Muir and his dog. (Corbis-Bettmann. Reproduced by permission.)

after the turn of the century. His writings are still widely read today by students, scholars, activists, and philosophers. In the opinion of most observers, the primary importance of Muir's writings lies not in their literary quality but in the fact that they persuaded a large number of Americans to regard scenic wilderness areas as irreplaceable **natural resources** which must be protected and preserved.

Mulch

Material applied to the surface of a **soil** to protect the soil or to improve the **environment** of the soil's surface. Mulch can be made from many different kinds of organic or inorganic materials like stones, bark, compost, leaves, wood chips, and manure. The benefits of using mulch include the following: protection of soil from **erosion**, evaporation reduction, increased water **infiltration**, reduction in weed seed germination, increased seed germination, and reduction of **compaction** of soil. *See also* Animal waste; Composting; Fertilizer; Soil organic matter; Soil texture; Topsoil

Multiple chemical sensitivity

Regarded by skeptics as a manifestation of "technophobia" and "chemophobia," multiple chemical sensitivity is a highly controversial disorder associated with low levels of environmental **chemicals** in general and volatile organic chemicals in particular. Sufferers experience fatigue, malaise, headache, dizziness, lack of concentration, and loss of memory, and are often so disabled that they cannot live or work except in completely chemical-free environments. Critics argue that this condition should not receive clinical recognition as a disease, insisting that the condition has no uniform cause or consistent, measurable features. Advocates for sufferers say it is a chronic condition marked by heightened sensitivity to even slight chemical exposures; and that multiple symptoms occur in multiple organ systems, usually caused by large "triggering" exposures such as to new carpeting that emits chemicals.

Multiple Use-Sustained Yield Act (1960)

On June 12, 1960, Congress passed the Multiple Use-Sustained Yield Act, designed to prevent the obliteration of national forests by **logging** and **water reclamation** projects. This law officially mandated the management of national forests to "best meet the needs of the American people." The forests were to be used not primarily for economic gain, but for a balanced combination of "outdoor **recreation**, range, timber, **watershed**, and **wildlife** and fish purposes."

The Multiple Use Act emerged from a strong history of diverse uses of the federal reserves. Early settlers assumed access to and free use of public lands. The text of the Sundry Civil Act of 1897 mandated that no public forest reservation was to be established except to improve and protect forests and water flow. The act also provided for free use of timber and stone and of all reservation waters by miners and resi-

dents. The Act of February 28, 1899, strengthened use policy by providing for recreational use of the reserves.

When the reserves were transferred from the General Land Office to the Bureau of Forestry, the Secretary of Agriculture signed a letter (actually written by **Gifford Pinchot**) dictating formal forest policy: "all the resources of the forest reserves are for use... you will see to it that the water, wood, and forage of the reserves are conserved and wisely used." The first and subsequent editions of the *Use Book*—an extensive guide to management and use of **national forest** lands—stated concisely that the aim of **Forest Service** policy was that "the timber, water, pasture, mineral and other resources of the forest reserves are for the use of the people."

The first use of the term "multiple use" appears to be in two Forest Service reports of 1933. That year's chief's report reaffirmed that the "principle to govern the use of land...is multiple-purpose use." The "National Plan for American Forestry" (the Copeland Report) emphasized that "the peculiar and highly important multiple use characteristics of forest land [involve] five major uses--timber production, watershed protection, recreation, production of forage, and **conservation** of wildlife."

Multiple use has always been controversial. Some critics argued that multiple uses meant that the Forest Service was losing sight of its original protective function: a 1927 article in the *Outlook* claimed that "the Forest Service will have to be called from its enthusiasm for entertaining visitors to the original but more somber work of forestry." Many similar statements can be identified. A writer in the *Journal of Forestry* in 1946 went so far as to propose separating all the lands in each use class, consolidating each type into a separate bureau under one cabinet officer. The **Sierra Club** proposed a vast land exchange in 1959, hoping to move scenic areas out of the Forest Service and into the **U.S. Department of the Interior**.

Critics have argued, and feel that subsequent policy and events on the ground bear them out, that the Multiple Use Act did not reduce confusion because it did not eliminate water and timber as priority uses. Proponents of the act feel that it did give statutory authority to all uses as equal to timber and did give the other four uses more stature and **visibility**. *See also* Bureau of Land Management; Commercial fishing; Public Lands Council

Multi-species management

Multi-species management (MSM) specifies the development of a particular ecologically balanced assessment and operation in protecting fish and **wildlife**. Such protection of **species** and the **environment** that supports and sustains them relies on understanding the species' interaction with each other, and within a particular environment—whether a body of water, a marshland, or other natural surroundings. The **Environmental Protection Agency** (EPA) and the U.S. **Fish and Wildlife Service** (FWS) play key roles in overseeing this management due to the imperative for restoring and maintaining an effective **ecosystem**. In concert with the Endangerd Species Act (ESA), the focus in MSM is on lessening the possibility of certain species being added to the *Endangered Species* list in addition to the management of those species currently thriving.

In the fall of 2002, the College of Foresty at Oregon State University was hosting a symposium, *Innovations in Species Conservation* for the purpose of studying the issues of strategies for conserving species, ecological risks and uncertainties associated with certain strategies, and examining social and legal contexts of **conservation** strategies. The announcement for the symposium pointed out that, "In the past, efforts to conserve species have focused on providing appropriate **habitat** for, and population management of, individual high-profile species protected by laws and regulations. Some regional plans have been designed to conserve a broad array of species and biological diversity by specifying protection of rare and uncommon species." But according to the research indicated, there also remain some questions regarding the multi-species direction. The discussion goes on to say that, "Such approaches have proven to be complex and expensive, and have placed constraints on the ability to meet other important management objectives. Multiple-species or ecosystem approaches addressing species assemblages at regional scales may be more efficient and lessen management constraints, but the degree to which they protect individual species rests more on hypothesis than on systematic testing. Such multi-system approaches may also be more susceptible to legal challenges due to a lower level of certainty regarding the outcomes for a particular species."

Still, by 2002, evidence continues to emerge from extensive research over the last few decades, that MSM has produced some results that indicate success. The theory is that if one species, or aspect of an ecosystem is out of balance, therefore the entire system is out of balance. In a 1999 article

written by Dick Monroe, Vice President of Environmental Affairs for Darden Restaurants, he noted that global management of **whales** and **seals** directly affected the seafood and restaurant industry. It was his concern—in opposition to the philosophy of many **animal rights** and whale watch groups—that whales were consuming between three and six times the total annual catch of all commercial fisheries. He noted that an MSM approach must be supported because when the focus is simply on one species, another is sure to lose out and the supply depleted.

The Kyoto Treaty—the United States backed out of support of the treaty under the George W. Bush administration in 2001—also specifies MSM as one of its components. Throughout the United States, under the sponsorship of various government and private agencies, MSM had become an important research approach to environmental concerns. It represents a worldwide effort as well as one for the United States—especially in countries that rely heavily on the fishing industry as a support of their economic system. In Norway, for instance, in order to manage certain fishing stocks in the Barents Sea, it was crucial for researchers to determine how much of that species waaas eaten by another fish. The Institute of Marine Research in Bergen (Norway) developed a multi-species model to address this issue, among others. In managing the stock of capelin, it was crucial to know how much of it was consumed by the cod, and also in marine mammals. Beginning in 1987, Norwegian and Russian scientists cooperated in collecting this information. By 1993, the groups had collected samples from the stomach content of over 50,000 cod. This example of the mechanism by which MSM operates is typical of similar programs throughout the United States, and around the world.

Municipal solid waste

Americans generate about 160 million tons of municipal **solid waste** (MSW) per year not counting construction debris. That's enough **garbage** to fill a convoy of trash trucks reaching half way from the earth to the moon. That much garbage equals about 1,300 pounds (590 kg) of waste per year for every person in the United States, or about 25 pounds (11.5 kg) per person per week. The **Environmental Protection Agency** (EPA) tells us that every year Americans throw away 60 billion cans, 28 million bottles, 4 million tons of plastic, 40 million tons of paper, 100 million tires, and 3 million cars. If growth in disposal rates continue, Americans may generate nearly 2,000 million tons of MSW by the year 2000.

Municipal solid waste is waste generated by households, commercial businesses, institutions, light industry and agricultural enterprises and nontoxic wastes from hospitals and laboratories. Municipal waste is composed of (in order of volume contribution) paper/packaging, **yard waste**, **food waste**, magazines/newspapers, **plastics**, glass, wood/fabric, **disposable diapers**, and other contributions such as tires, appliances, and nontoxic home maintenance supplies. In addition to this relatively benign list, there is other municipal waste that ends up in a **landfill** inappropriately—e.g., leftover paint, crankcase oil, batteries, and parts of some appliances such as capacitors in refrigerators and air conditioners. In some cases sewage **sludge** from the local **wastewater** treatment facility ends up in the landfill with other municipal solid waste. It is these inappropriate wastes that cause concern in the minds of local officials as they ponder the siting of landfills.

Since municipal waste is a non-homogeneous stream of materials, its impact is unpredictable. Although only about two percent of the municipal **waste stream** is toxic, even that small amount has the potential of contaminating large amounts of **groundwater** if the leachate from landfills reach the **aquifer**. In addition, landfills situated near a lake or a stream can leak laterally and contaminate surface water. In spite of the fact that the engineering of landfills has become much more sophisticated in the last 10 years, there is still sincere concern about the impact of municipal waste on ground and surface water.

Several methods for managing municipal solid waste have been designed and implemented over the last 20 years. In the United States, 80% or more of the municipal solid waste ends up in landfills, about 10% is incinerated, and about 11% is recycled. Waste-to-energy **incineration** is an option aimed at reducing the volume of municipal waste and producing an ongoing supply of energy for nearby markets. The complication of this treatment method is the ash residue and its disposal as well as **air pollution**. Probably the most desirable management technique for MSW is **recycling**.

Recycling captures the embodied energy in the products to be discarded. The conversion of the waste stream into a second or third generation of usable products is far superior to simple volume destruction or land burial. Unfortunately, recycling requires behavioral change on the part of the waste generator and behavioral and infrastructure change on the part of industry in order to create markets for post consumer materials. Individuals must learn to clean and separate household garbage and make it ready for recycling. Industry must make the investment to change manufacturing processes to accommodate a heterogeneous "raw" material.

Even more desirable than recycling is source reduction and **reuse** of household products and industrial and business supplies. Buying durable and re-usable products reduces the volume of the MSW stream. Packaging that can be reused after the product has been used is another way of shrinking municipal solid waste volume. In some European countries like Germany, manufacturers are required to take back all their packaging materials.

The cost of MSW disposal has increased dramatically over the last 10 years. Part of this cost is due to the pressure being put on fewer and fewer landfills as older landfills close. Many metropolitan areas of the United States have exhausted their landfill capacity and are transporting waste into rural areas. Unfortunately, in rural areas the volume of MSW is not sufficient for landfill companies to make the investment and build state-of-the-art landfills. Furthermore there is increasing concern that many towns and cities are dumping their MSW in areas where people have less political power or need the revenue from tipping fees. Consequently the management of waste has become a social issue as well as an environmental concern.

Currently there are approximately 3,500 licensed landfills operating in the United States. Tipping fees have increased as have transport fees. States are transporting MSW hundreds of miles to other states because they can't build landfills due to citizen opposition. The NIMBY (**Not In My Backyard**) syndrome makes it difficult to create more landfills. **Waste management** companies are offering extensive incentive packages to local communities in order to get approval for landfill siting. Yet, almost without exception, local citizens attempt to block the construction of landfills.

Municipal solid waste is a renewable resource. We will always have new supplies of it. Even though many citizens are beginning to turn to nondisposable items and there is a real effort to launch recycling programs nationwide, we are still faced with an increasing volume of municipal waste. It is a complex problem that will require behavioral change on the part of individuals, a commitment on the part of local city planners, and an investment on the part of industry in order to recycle the waste stream. *See also* Medical waste

Municipal solid waste composting

Municipal Solid Waste (MSW) composting is a rapidly growing method of solid **waste management** in the United States. MSW includes the residential, commercial, and institutional **solid waste** generated within a community. MSW **composting** is the process by which the organic, **biodegradable** portion of MSW is microbiologically degraded under **aerobic** conditions.

During the process of degradation, bacteria are used to decompose and break down the organic matter into water and **carbon dioxide**, which produces large amounts of heat and water vapor in the process. Given sufficient oxygen and optimum temperatures, the composting process achieves a high degree of volume reduction and also generates a stable

end product called compost that can be used for mulching, **soil** amendment, and soil enhancement. As a form of solid waste management, MSW composting reduces the amount of waste that would otherwise end up in landfills.

Although composting has been practiced by humans for centuries, the concept of composting mixed solid waste as a form of large-scale solid waste management is still in an early stage of development in the United States. MSW generally consists of a mixture of organic compostable materials such as **food waste** and paper and inert, nonbiodegradable materials such as **plastics** and glass. The introduction of non-compostable materials may pose problems in materials handling during the composting process and also hinder the formation of a uniform, homogeneous compost. Therefore, in order to practice MSW composting as a form of waste management, the composting system must be designed to remove the non-compostable materials either by presorting and screening or by sifting and removal at the end of the process.

The three most common methods of MSW composting are closed in-vessel, windrow, and static aerated pile composting. The method of choice depends on the volume of waste to be composted and the availability of space for composting. In the closed in-vessel method, the MSW is physically contained within large drums or cylinders and all necessary **aeration** and agitation is supplied to the vessel. In windrows, the MSW is heaped in long rows of material approximately four to seven feet high. Air and ventilation are supplied by physically turning over the piles with mechanical windrow turners. In static aerated compost piles, the MSW piles are not physically agitated, rather air is supplied and excess heat is removed by a system of sensors and pipes within the pile. In all cases, the goal is to ensure a steady, optimum rate of composting by providing adequate oxygen and ventilation to remove excess heat and water so that microbiological action is not impaired. When there is insufficient air supply, microbial action is unable to fully decompose the waste and the piles become **anaerobic** and unpleasant odors and putrefaction may result. Strong neighborhood complaints against odors is the single most common reason for the failure and shutdown of composting plants.

In the United States, numerous, small-scale, pilot projects have demonstrated the feasibility of MSW composting for townships and municipalities. However, there are relatively few operations that successfully carry out MSW composting on a large, commercial scale. The operational large-scale facilities are located mainly in Florida and Minnesota, two states that have traditionally shown interest in innovative waste management options. *See also* Aerobic sludge digestion; Solid waste incineration; Solid waste recycling and recovery; Waste reduction

Mutagen

Any agent, chemical or physical, that has the potential for inducing permanent change to the genetic material of an organism by altering its DNA. The alteration may be either a point **mutation** (nucleotide substitution, insertion, or deletion) or a chromosome aberration (translocation, inversion, or altered chromosome complement). There are long lists of chemical mutagens which include such diverse agents as formaldehyde, mustard gas, triethylenemelamine, **vinyl chloride**, **aflatoxin** B, benzo(a)pyrene, and acridine orange. Chemical mutagens may be direct acting, or they may have to be converted by metabolic activity to the ultimate mutagen. Physical mutagens include (but are not limited to) x rays and **ultraviolet radiation**. *See also* Agent Orange; Birth defects; Chemicals; Gene pool; Genetic engineering; Love Canal, New York

Mutation

A mutation is a change in the DNA of an organism, which is genetically transmitted, and may give rise to a heritable variation. Mutagens, substances that have the competence to produce a mutation, may be subject to chromosomal changes such as deletions, translocations, or inversions. Mutations may also be more subtle, resulting in changes of only one or a few nucleotides in the sequence of DNA. These more subtle mutations are called as "point mutations," and it is these that most people refer to when discussing mutation.

Ordinarily, mutation is thought of as a genetic change that results in alterations in a subsequent generation. Germinal tissue, which gives rise to spermatozoa and ova, is the tissue in which such mutations occur. However, mutations can arise in many cell types in addition to the germ line, and these changes to non-germinal DNA are referred to as somatic mutations. Although somatic mutations are not passed to subsequent generations, they are not less important than germinal mutations. **Ionizing radiation** and certain **chemicals** can have mutagenic effects on somatic cells which often result in **cancer**.

A six-legged green frog—the result of a genetic mutation. (JLM Visuals. Reproduced by permission.)

Mutations may be either spontaneous or induced. The term spontaneous is perhaps misleading; even these mutations have a physical basis in cosmic rays, natural **background radiation**, or simply kinetic effects of molecular motion. Induced mutations ensue from known exposure to a diversity of chemicals and certain ionizing radiations.

DNA is composed of a linear array of nucleotides, which are translocated through RNA into protein. The genetic code consists of consecutive nucleotide triplets which correspond to particular amino acids, and it may be altered by substitution, insertion, or deletion of individual nucleotides. Substitution of a nucleotide in some cases can be inconsequential, since the substituted nucleotide may specify an amino **acid** which does not affect the function of the protein. On the other hand, substitution of one nucleotide for another one can result in a protein gene product with a changed amino acid sequence that has a major biological effect. An example of such a single nucleotide substitution is sickle cell hemoglobin, which differs from normal hemoglobin by a single amino acid. The substitution of a valine for a glutamic acid in the mutant hemoglobin molecule results in sickle cell disease, which is characterized by chronic hemolytic **anemia**.

The insertion or deletion of a single nucleotide pair results in what is known as a frameshift mutation; this is because the mutation changes the sequence of molecules beyond the point at which it occurs, causing them to be read in different groups of three. Consequently, there is a miscoding of the nucleotides into their gene product. Such proteins are usually shortened in length and no longer functional.

Mutagenic Effects of Environmental Contaminants. New York: Academic Press, 1972.

Mutualism

A mutualism is a **symbiosis** where two or more **species** gain mutual benefit from their interactions, and suffer negative impacts when the mutualistic interactions are prevented from occurring. Mutualism is a form of symbiosis where the interactions are frequently obligatory, with neither species being capable of surviving without the other. A well-known example of mutualism is the relationship between certain species of algae or blue-green bacteria and **fungi** that results in organisms called **lichens**. The fungal member of the relationship provides a spatial **habitat** for the algae, which in turn provide energy from **photosynthesis** to the fungus. Mutualistic interactions are thought to be the origin of the many cell organelles like mitochondria and chloroplasts, which may have resulted from the acquisition of free-living **phytoplankton** and other single-celled organisms by host species. Both the incorporated cell and the host soon evolved so that neither could exist without the other.

see **Megawatt**

Mycorrhiza

Refers to a close, symbiotic relationship between a fungus and the roots of a higher plant. Mycorrhiza (from the Greek *myketos* meaning fungus and *rhiza* meaning root) are common among trees in temperate and tropical forests. There are generally two forms—ectomycorrhiza, where the fungus forms a sheath around the plant roots, and endomycorrhiza, where the fungus penetrates into the cells of the plant roots. In both cases, the fungus acts as extended roots for the plant and therefore increase its total surface area. This allows for greater **adsorption** of water and nutrients vital to growth.

Mycorrhiza even allow plants to utilize nutrients bound up in silicate minerals and phosphate-containing rocks that are normally unavailable to plant roots. They also can stimulate the plants to produce **chemicals** that hinder invading pathogens in the **soil**. In addition to the physical support, the mycorrhiza obtain carbohydrates from the higher, photosynthetic plant. This obligate relationship between **fungi** and plant roots is especially important in nutrient-impoverished soils. In fact, many trees will not grow without mycorrhiza. *See also* Symbiosis; Temperate rain forest; Tropical rain forest

Mycotoxin

Mycotoxins are toxic biochemical substances produced by **fungi**. They are produced on grains, fishmeal, peanuts, and many other substances, including all kinds of decaying vegetation. Mycotoxins are produced by several **species** of fungi—especially *Aspergillus*, *Penicillium*, and *Fusarium*—under appropriate environmental conditions of temperature, moisture, and oxygen on crops in the field or in storage bins. In recent years, research on this subject has indicated considerable specialization in mycotoxin production by fungi. For example, aflatoxins B_1, B_2, G_1, and G_2 are relatively similar mycotoxins produced by the fungus *Aspergillus flavus* under conditions of temperatures ranging from 80-100°F (27-38°C) and 18-20% moisture in the grain. Aflatoxins are among the most potent carcinogens among naturally occurring products. Head scab on wheat in the field is produced by the fungus *Fusarium graminearum* which produces a mycotoxin known as DON (*deoxynivalenol*), also known as Vomitoxin.

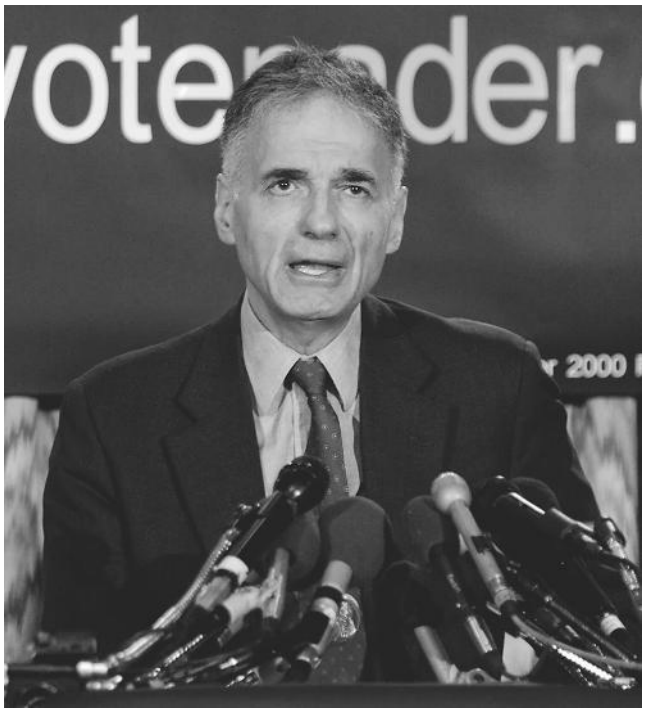
Ralph Nader (1934 –)



American consumer advocate

Born in Connecticut, Ralph Nader is the son of Lebanese immigrants who emphasized citizenship and democracy and stressed the importance of justice rather than power. Nader earned his bachelor's degree in government and economics from Princeton University in 1955 and his law degree from Harvard University in 1958, having served as editor of the prestigious *Harvard Law Record*. Nader reads some 15 publications daily and speaks several languages, including Arabic, Chinese, and Russian.

Nader published his first article, "American Cars: Designed for Death," as editor of the *Harvard Law Record*. He later made his reputation with *Unsafe at Any Speed* (1965), a condemnation of the American **automobile** industry's record on safety. The book was initially commissioned by then-assistant secretary of labor Daniel Patrick Moynihan in 1963 as a report to congress, and was then brought out as a trade book by a small publisher. In the book Nader condemned U.S. automakers for valuing style over safety in developing their products and specifically targeted General Motors and its Chevrolet Corvair. General Motors hired a private investigator to dig dirt on Nader, resulting in a scandal that propelled the book to best-seller status. The controversy that *Unsafe at Any Speed* generated led to passage of the Traffic and Motor Vehicle Safety Act of 1966, which gave the government the right to enact and regulate safety standards for all automobiles sold in the United States.

With the money and fame generated by his book, Nader went on to champion a wide variety of causes. He played a key role in the establishment of the **Occupational Safety and Health Administration** (OSHA) as well as the Consumer Product Safety Commission. One of his most important victories was the establishment of the **Environmental Protection Agency** (EPA) in 1970, during the Nixon administration. He also worked to ensure passage of the Freedom of Information Act (1974). Nader got many young people to work on consumer and environmental issues through the Public Information Research Groups found on college campuses across the country. To assist him in his far-reaching investigative efforts, Nader created a watchdog team, known as Nader's Raiders. This group of lawyers was the core of what became the Center for Study of Responsive Law (CSRL), which has been Nader's headquarters since 1968. A network of public interest organizations branched off from CSRL, including Public Citizen, Health Research Group, Critical Mass Energy Project, and Congress Watch. Other groups have been established by Nader's associates, and though not run by Nader himself, they follow the same ideals as CSRL and work toward similar goals. Among these groups are: the Clean Water Action Project, the Center for Auto Safety, and the **Center for Science in the Public Interest**. A 1971 Harris poll placed Nader as the sixth most popular figure in the nation, and he is still recognized as the most important consumer advocate in the country.

Nader was at the height of his influence during the 1970s, but through the 1980s and early 1990s he was less in the public eye. The Reagan years saw a loosening of the regulations for which he had fought, and Nader himself suffered many personal setbacks, including the death of his brother and his own neurological illness. In 1987, Nader vigorously campaigned for Proposition 103 in California, which would roll back automobile insurance rates. The bill passed and exit polls showed that Nader's efforts had made the difference. Though he had been asked to run for president by the Beatles' John Lennon and by writer Gore Vidal in the early 1970s, Nader had always claimed that he needed to stay outside government in order to reform it. This changed in 1992, when Nader asked voters to write him in on the presidential ballot. He voiced his disgust at the two major parties, the Republicans and the Democrats, and asked

Ralph Nader. (AP/Wide World Photos. Reproduced by permission.)

to be considered as a "none-of-the-above" option. In 1996 he made a wider effort as the candidate for the Green Party. Nader was on the ballot in 21 states and polled a minuscule.68 percent of the vote (Reform Party candidate Ross Perot by contrast earned over 8 percent of the total national vote). Nader ran an informal campaign, mainly touring college campuses, and he did not appear to have much of an effect on the election. In 2000 Nader ran a much more concerted campaign, again as the Green Party candidate. He famously declared the leading candidates, George W. Bush and Al Gore to be "tweedledum and tweedledee," meaning they were virtually indistinguishable because of their support for corporate interests. Late in the campaign, it appeared that Gore and Bush were tied, and the Democratic party began to excoriate Nader. Though it appeared that Nader might siphon crucial votes away from Gore and thus let Bush win, Nader refused to alter his position or throw his support to Gore. **Environmentalism** became a key issue in the three-way race. Though Gore had a strong record on the **environment** and Bush what might be called an abyssmal one, Nader continued to criticize Gore for not having done enough. Finally, Gore won the popular vote with 48.39%, Bush came in with 47.88%, and Nader with 2.72%. But the election went to Bush after the Supreme Court halted the recount of contested Florida ballots, and that state's electoral college votes put Bush in the White House. Nader had won some 97,000 votes in Florida, and arguably if these votes had all gone to Gore, the outcome of the presidential race would have been different.

After the election, Nader was anathemized in some circles, and blamed for Gore's loss. Nader claimed to have no regrets except that he had not gotten at least 5% of the vote, which would have qualified the Green Party for federal matching funds for an election campaign in 2004. Nader published a memoir about the campaign, called *Crashing the Party: How to Tell the Truth and Still Run for President.* He refused to speculate about whether he would run for president again.

Dr. Arne Naess (1912 –)

Norwegian philosopher and naturalist

Arne Naess is a noted mountaineer and philosopher and the founder of the **deep ecology** movement. He was born to Ragnar and Christine Naess in Oslo, Norway, on January 27, 1912, the youngest of five children. Naess was an introspective child, and he displayed an early interest in logic and philosophy. After undergraduate work at the Sorbonne in Paris, he did graduate work at the University of Vienna, the University of California, Berkeley, and the University of Oslo. While in Vienna, his interests in logic, language, and methodology drew him to the Vienna Circle of logical empiricism. He was awarded the Ph.D. in philosophy from the University of Oslo in 1938.

A year later, in 1939, Naess was made full professor of philosophy at the same university. He promptly reorganized Norwegian higher education, making the history of ideas a prerequisite for all academic specializations and encouraging greater conceptual sophistication and tolerance. From the beginning, Naess was interested in empirical semantics, that is, how ordinary persons use words to communicate. In *"Truth" as Conceived by Those Who Are Not Professional Philosophers* (1939), he was one of the first to use statistical methods

and questionnaires to survey philosophical beliefs. Shortly after his appointment at the university, the Germans occupied Norway. Naess resisted any changes in academic routine, insisting that education be separate from politics. The increasing brutality of the Quisling regime, however, impelled him to join the **resistance** movement. While in the resistance he helped avert the shipment of thousands of university students to concentration camps. Immediately after the war, he confronted Nazi atrocities by mediating conversations between the families of torture victims and their pro-Nazi Norwegian victimizers.

In the post-War period, Naess's academic interests and accomplishments were many and varied. He continued his work on language and communication in *Interpretation and Preciseness* (1953) and *Communication and Argument* (1966), concluding that communication is not based on a precise and shared language. Rather we understand words, sentences, and intentions by interpreting their meaning. Language is thus a double-edged sword. Communication is often difficult and requires successive interpretations. Even so, the ambiguity of language allows for a tremendous flexibility in verbal meaning and content. Because of his work in communication and his resistance to the Nazis, Naess was selected by the United Nations Educational, Scientific and Cultural Organization [UNESCO] in 1949 to explore the meanings of democracy. This project resulted in *Democracy, Ideology and Objectivity* (1956). In 1958, he founded the journal *Inquiry*, serving as its editor until 1976. The magazine explores the relations of philosophy, science, and society, especially as they reflect normative assumptions and implications. He also published on diverse topics, including Gandhian nonviolence, the philosophies of science, and the Dutch philosopher Baruch Spinoza (1632–1677). These works include *Gandhi and the Nuclear Age* (1965), *Skepticism* (1968), *Four Modern Philosophers: Carnap, Wittgenstein, Heidegger, Sartre* (1968), *The Pluralist and Possibilist Aspect of the Scientific Enterprise* (1972), and *Freedom, Emotion and Self-Subsistence: The Structure of a Central Part of Spinoza's "Ethic"* (1972).

Naess began examining humanity's relationship with **nature** during the early 1970s. The genesis of this interest is best understood in the context of Norway's **environment**, culture, and politics. Nature, not humanity, dominates the landscape of Norway. The nation has the lowest population density in Europe, and over 90% of the land is undeveloped. As a consequence, the interior of Norway is relatively wild and diverse, a mixture of mountains, glaciers, fjords, forests, **tundra**, and small human settlements. Moreover, Norwegian culture deeply values nature; environmental themes are common in Norwegian literature, and the majority of Norwegians share a passion for outdoor activities and **recreation**. This passion is known as *friluftsliv*, meaning "open air life." Friluftsliv is widely touted as one means of reconnecting with the natural world. Norwegian environmental politics has been wracked by a **succession** of ecological and resource conflicts. These conflicts involve **predator control**, recreation areas, national parks, industrial **pollution**, **dams** and hydroelectric power, nuclear energy, North Sea oil, and economic development. During the 1960s Naess became deeply involved in environmental activism. Indeed, his participation in protests lead to his arrest for nonviolent civil disobedience. He even wrote a manual to help environmental and community activists participate in nonviolent resistance. Growing up, Naess was deeply moved by his experiences in the wild places of Norway. He became an avid mountaineer, leading several ascents of the Tirich Mir (25,300 ft [7700 m]) in the Hindu Kush range. In 1937, he built a small cabin near the final assent to the summit of Hallingskarvet, a mountain approximately 111 mi (180 km) northeast of Oslo. He named it *Tvergastein*, meaning "across the stones."

Since his retirement, Naess has published widely on environmental topics. His main contributions are in ecophilosophy, **environmental policy**, and **conservation biology**. The insight and controversy surrounding these writings have propelled him to the forefront of **environmental ethics** and politics.

Naess regards philosophy as "wisdom in action." He notes that many policy decisions are "made in a state of philosophical stupor" wherein narrow and short-term goals are all that is considered or recommended. Lucid thinking and clear communication help widen and lengthen the options available at any point in time. Naess describes this work as a labor in "ecophilosophy," that is, an inquiry where philosophy is used to study the natural world and humanity's relationship to it. Recalling the ambiguity of language and communication, he distinguishes ecophilosophy from ecosophy—a personal philosophy whose conceptions guide one's conduct toward nature and human beings. While important elements of our ecosophies may be shared, we each proceed from assumptions, norms, and hypotheses that vary in substance and/or interpretation. Of central importance to Naess's exploration of ecophilosophy are norms and beliefs about what one should or ought to do based on what is prudent or ethical. Norms play a leading role in any ecophilosophy. While science may explain nature and **human ecology**, it is norms that justify and motivate our actions in the natural world. Along with the concept of norms, Naess stresses the importance of depth. By depth, Naess means reflecting deeply on our concepts, emotions and experiences of nature, as well as digging to the cultural, personal, and social roots of our environmental problems. Thinking deeply means taking a broad and incisive look at our values, lifestyles, and community life. In so doing, we discover if our way of life is consistent with our most deeply felt norms.

An ecophilosophy which deeply investigates and clarifies its norms is called a "deep ecological philosophy." A social movement that incorporates this process, shares significant norms, and seeks deep personal and social change is termed "deep **ecology** movement." Naess coined the term "deep ecology" in 1973, intending to highlight the importance of norms and social change in environmental decision-making. He also coined the term "shallow ecology" to describe what he considered short-term technological solutions to environmental concerns. Naess's own ecophilosophy is called "Ecosophy T." The "T" symbolizes Tvergastein. **Ecosophy** T stresses a number of themes, including the **intrinsic value** of nature, the importance of cultural and natural diversity, and the norm of self-realization for persons, cultures, and non-human life-forms. Naess offers his ecosophy as a tentative template, encouraging others to construct their own ecosophies.

Deep ecology is therefore a rubric representing many philosophies and practices, each differing in significant ways. Naess encourages this diversity, recognizing that many mutually acceptable interpretations of deep ecology are possible. On the whole, therefore, Naess is philosophically and environmentally non-dogmatic. He avoids rigid dichotomies pitting individual versus social accounts, liberal versus radical solutions, or **wilderness** versus justice concerns. To paraphrase Naess, "the frontier is long and there are many places to stand." Some may focus their thoughts and efforts on nature, others on society, still others on culture. According to Naess, these are legitimate and necessary foci and should be encouraged as separate endeavors and joint undertakings.

Nagasaki, Japan

Nagasaki is a harbor city located at the southwestern tip of Japan. It is Japan's oldest open port. Traders from the western world started arriving in the mid-sixteenth century. It became a major shipbuilding center by the twentieth century. It was the second city to be devastated by an atomic bomb which was dropped on August 9, 1945, just 3 days after the bomb that destroyed Hiroshima. The bomb that was dropped at Nagasaki resulted in 35,000-40,000 men, women, and children killed with an equal number injured. Like Hiroshima, most of the city was destroyed. The Nagasaki survivors of the atomic bomb have an increased risk for radiation-induced **cancer** and are part of a continuing study by the Atomic Bomb Casualty Commission which is now known as the Radiation Effects Research Foundation (RERF). The city was rebuilt after the end of World War II and is now a tourist attraction.

National Academy of Sciences

The National Academy of Sciences (NAS) is a private, nonprofit, self-governing organization that is responsibility for advising the U.S. federal government, upon request and without fee, on questions of science and technology that affect policy decisions. NAS was created in 1863 by a congressional charter approved by President Abraham Lincoln. Under this same charter, the institution was expanded to include sister organizations: in 1916 the **National Research Council** was established, in 1964 the National Academy of Engineering, and in 1970 the Institute of Medicine. Collectively these organizations are called the National Academies.

NAS publishes a scholarly journal, *Proceedings of the National Academy of Sciences*, organizes symposia, and calls meetings on issues of national importance and urgency. Most of its study projects are conducted by the National Research Council rather than by committees within NAS. However, NAS sponsors two committees, the the Committee on International Security and Arms Control and the Committee on Human Rights.

NAS is an honorary society that elects new members each year, in recognition of their distinguished and continuing achievements in original research. New members are nominated and voted on by existing members. Election to membership is one of the highest honors that a scientist can receive. As of early 1999, NAS had 1,798 Regular Members, 87 Members Emeriti, and 310 Foreign Associates. More

The aftermath from the atom bomb that was dropped on Nagasaki during World War II. (UPI/Corbis-Bettmann. Reproduced by permission.)

than 170 members have won Nobel Prizes. No formal duties are required of members, but they are invited to participate in the governance and advisory activities of NAS and the National Research Council. NAS is governed by a Council, comprised of twelve councilors and five officers elected from the Academy membership. Committee members are not paid for their work, but are reimbursed for travel and subsistence costs. Foreign Associates are elected using the same standards that apply to Regular Members, but do not vote in the election of new members or in other deliberations of the NAS.

NAS does not receive federal appropriations directly, but is funded through contracts and grants with appropriations made available to federal agencies. Most of the work done by NAS is at the request of federal agencies. NAS is responsive to requests from both the executive and legislative branches of government for guidance on scientific issues.

NAS also cooperates with foreign scientific organizations. Officers of NAS meet with officers of the Royal Society of England every two or three years. NAS represents U.S. scientists as an institutional member of the International Council of Scientific Unions.

The work and service of NAS and its sister organizations have resulted in significant and lasting improvement in the health, education, and welfare of U.S. citizens.

National Air Toxics Information Clearinghouse

The National Air Toxics Information Clearinghouse (NATIC) is a program administered by the **Environmental Protection Agency** (EPA). This information network was developed by the EPA to provide state and federal **air pollution control** experts with **air pollution** data. The computerized data base is headquartered in North Carolina, but air **pollution control** officers nationwide are able to access the data.

NATIC is a "one-stop shop" for emissions data for state enforcement officers, according to the EPA. Included on the network is information on air toxics programs, **ambient air** quality standards, **pollution** research, non-health related impact of air pollution, permits, emissions inventories, and ambient **air quality** monitoring programs.

National Ambient Air Quality Standard

The key to national **air pollution control** policy since the passage of the **Clean Air Act** amendments of 1970 are the National Ambient Air Quality Standards (NAAQSs). Under this law, the **Environmental Protection Agency** (EPA) had to establish NAAQSs for six of the most common air pollutants, sometimes referred to as criteria pollutants, by April 1971. Included are **carbon monoxide**, **lead** (added in 1977), **nitrogen oxides**, **ozone**, **particulate** matter, and **sulfur dioxide**. **Hydrocarbons** originally appeared on the list of pollutants, but were removed in 1978 since they were adequately regulated through the ozone standard. The provisions of the law allow the EPA to identify additional substances as pollutants and add them to the list.

For each of these pollutants, primary and **secondary standards** are set. The **primary standards** are designed to protect human health. Secondary standards are to protect crops, forests, and buildings if the primary standards are not capable of doing so; a secondary standard presently exists only for sulfur dioxide. These standards apply uniformly throughout the country, in each of 247 Air Quality Control Regions. All parts of the country were required to meet the NAAQSs by 1975, but this deadline was extended, in some cases, to the year 2010. The states monitor **air pollution**, enforce the standards, and can implement stricter standards than the NAAQSs if they desire.

The primary standards must be established at levels that would "provide an adequate margin of safety ... to protect the public ... from any known or anticipated adverse effects associated with such air pollutant[s] in the ambient air." This phrase was based on the belief that there is a threshold effect of **pollution**: pollution levels below the threshold are safe, levels above are unsafe. Although such an approach to setting the standards reflected scientific knowledge at the time, more recent research suggests that such a threshold probably does not exist. That is, pollution at any level is unsafe. The NAAQSs are also to be established without consideration of how much it will cost to achieve them; they are to be based on the **Best Available Control Technology** (BAT). The secondary standards are to "protect the public welfare from any known or anticipated adverse effects."

The NAAQSs are established based on the EPA's "criteria documents," which summarize the effect on human health caused by each pollutant, based on current scientific knowledge. The standards are usually expressed in parts of pollutant per million parts of air and vary in the duration of time a pollutant can be allowed into the **environment**, so that only a limited amount of contaminant may be emitted per hour, week, or year, for example. The 1977 Clean Air Act amendments require the EPA to submit criteria documents to the Clean Air Scientific Advisory Committee and the EPA's Science Advisory Board for review. Several revisions of the criteria documents are usually required. Although standards should be based on scientific evidence, politics often become involved as environmentalists and public health advocates battle industrial powers in setting standards.

The six criteria pollutants come from a variety of sources and have a variety of health effects. **Carbon** monoxide is a gas produced by the incomplete **combustion** of **fossil fuels**. It can lead to damage of the cardiovascular, nervous, and pulmonary systems, and can also cause problems with short-term attention span and sensory abilities.

Lead, a heavy metal, has been traced to many health effects, mainly brain damage leading to learning disabilities and retardation in children. Most of the lead found in the air came from **gasoline** fumes until a 1973 court case, *Natural Resources Defense Council v. EPA*, prompted its inclusion as a **criteria pollutant**. Lead levels in gasoline are now monitored.

Nitrogen oxide is formed primarily by fossil fuel combustion. It not only contributes to **acid rain** and the formation of ground-level ozone, but it has been linked to respiratory illness.

Ground-level ozone is produced by a combination of hydrocarbons and nitrogen oxides in the presence of sunlight, and heat. It is the prime component of **photochemical smog**, which can cause respiratory problems in humans, reduce crop yields, and cause forest damage. In 1979, the first revision of an original NAAQS slightly relaxed the photochemical oxidant standard and renamed it the ozone standard. Experts are currently debating whether this standard is low enough, and in 1991 the American Lung Associa-

tion sued the EPA for failure to review the ozone NAAQS in light of new evidence.

Particulate matter is composed of small pieces of solid and liquid matter, including soot, dust, and organic matter. It reduces **visibility** and can cause eye and throat irritation, respiratory ailments, and **cancer**. Through 1987, total suspended particulates were the basis of the NAAQS. In 1987, the standard was revised and based on particulate matter with an aerodynamic diameter of 10 micrometers or less (PM-10), which was identified as the main health risk.

Sulfur dioxide is a gas produced primarily by coal-burning utilities and other fossil fuel combustion. It is the chief cause of **acid** rain and can also cause respiratory problems.

To achieve the NAAQSs for these six pollutants, the Clean Air Act incorporated three strategies. First, the federal government would establish New Source Performance Standards (NSPSs) for stationary sources such as factories and **power plants**; they would also establish **emission standards** for mobile sources. Finally, the states would develop State Implementation Plans (SIPs) to address existing sources of air pollution. If the federal government determined that an SIP was not adequate to assure that the state would meet the NAAQSs, it could impose federal controls to meet them. According to the EPA, the SIPs must be designed to bring sub-standard air quality regions up to the NAAQSs, or to make sure any area already meeting the requirements continued to do so. The SIPs should prevent increased air pollution in areas of noncompliance, either by preventing significant expansions of existing industries or the opening of new plants. In order to allow economic development and growth in such non-attainment areas while still working to reduce air pollution, the 1977 amendments to the Clean Air Act required that new sources of pollution in non-attainment areas must control emissions to the **lowest achievable emission rate** (LAER) for that type of source and pollution and demonstrate that the new pollution would be offset by new **emission** reductions from existing sources in the area, reductions that went beyond existing permits and compliance plans. So, new sources were allowed, but only if the additional pollution were offset by reductions at existing sources.

Between 1978 and 1987, data collected nationally at 84 to 1,726 sites (varying for each pollutant) indicate that annual average concentrations of total suspended particulates fell by 21%, sulfur dioxide levels fell by 35%, carbon monoxide levels fell by 32%, lead levels fell by 88%, nitrogen dioxide levels fell by 12%, and ozone levels fell by 9%. With the exception of ozone, the average concentrations are below the NAAQSs. It is unclear how these reductions have improved human health conditions, but illnesses due to chronic lead exposure are down. Ozone probably causes the most health problems in affected areas, since the NAAQS for it is most often exceeded. Due to other complex factors, though, it is unclear how much of a problem it is.

Though the Clean Air Act allows one violation per year for each of the one-hour, eight-hour, and twenty-four hour NAAQSs for each pollutant, most urban areas, called non-attainment areas, violate standards much more often. For example, in Los Angeles the ozone standard was exceeded an average of 123 times annually in 1983, 1984, and 1985. As of 1989, 341 counties had ozone non-attainment, 317 had particulate non-attainment, 123 had carbon monoxide non-attainment, sixty-seven had sulfur dioxide non-attainment, and four had nitrogen dioxide non-attainment. A total of 529 counties had not met standards on at least one criteria pollutant.

The 1990 amendments to the Clean Air Act dealt with the problem of such non-attainment areas. Six categories of ozone non-attainment were established, ranging from marginal to extreme, and two categories for both carbon monoxide and particulate matter were established. Deadlines to achieve the NAAQSs were extended from three to twenty years. Increased restrictions were required in non-attainment areas; existing controls were tightened and smaller sources were made subject to regulation. Also, annual reduction goals were mandated. Areas considered to have made inadequate progress toward reaching attainment are subjected to stringent regulations on new plants and limited use of federal highway funds. *See also* Air pollution control; Air pollution index; Air quality criteria; Heavy metals and heavy metal poisoning; Nonpoint source; Point source

National Audubon Society

The National Audubon Society (NAS) is one of the largest and oldest **conservation** organizations in the world. Founded in New York City in February 1886, its original purpose was to protect American birds from destruction for the millinery trade. Many **species** of birds were being killed and sold as adornments to women's hat and bonnets, as well as other clothing. The first preservation battle taken on by

the NAS was the snowy egret—a white, wading marshland bird—whose long plumes were in high demand. The group was instrumental in securing passage of the New York Bird Law in 1886, an act for the preservation of the state's avifauna.

The NAS was named after John James Audubon, the nineteenth-century artist and naturalist. Audubon was not a conservationist; he often killed dozens of birds to get a single individual that was right for his paintings. But he had published his life-sized renderings of all the birds in North America in 1850, and his name was the one most closely associated with birds when the society was founded.

The protection of **wildlife** and habitats continues to be the primary focus of the NAS. Since their founding, much of their conservation work has been accomplished through education. Their *Audubon* magazine is perhaps their most important educational tool. They also publish *American Birds*, which records many of the field observations reported to the society from around the country.

One of the most important observations published in *American Birds* is the data recorded on Christmas Bird Counts, an annual winter bird census maintained by NAS since 1900. During a three-week period from December to early January, teams of observers count and record every different species of bird observed within a 24-hour period in a designated circle, 15 mi (24 km) in diameter. The count circles remain constant from year to year which allows for comparison of data collected. The first circle was Central Park in New York City; the number of circles have grown from one to over 1,600 in recent years. Thousands of people participate in this annual event.

Additional educational and conservation programs have proven successful for NAS over the years, including a nature club for children and a series of **ecology** camps for the field study of different ecosystems in North America. The society has also produced nature films and nationally televised programs on environmental issues facing the world today. NAS also addresses these issues through lobbying on a national level in Washington, D.C., and on regional and local levels by members of the several hundred local Audubon Societies, clubs, and state coalitions nationwide. With over half a million environmentally-conscious members, the National Audubon Society continues to make a difference in the battle to conserve the natural world and the wildlife in it.

National Emission Standards for Hazardous Air Pollutants

Emission standards for hazardous air pollutants are set forth in the Section 112 of the **Clean Air Act** of 1970 and the **National Ambient Air Quality Standard**. Section 112 directed the **Environmental Protection Agency** (EPA) to issue a list of hazardous pollutants that were to be regulated. However, the provisions of the 1970 Clean Air Act that were designed to regulate hazardous pollutants proved to be ineffective. Although more than 300 toxic substances are known to be emitted into the air, between 1970 and 1990 **emission** standards were established for only eight substances: **asbestos**, **benzene**, beryllium, coke oven emissions, inorganic **arsenic**, **mercury**, **radionuclides**, and **vinyl chloride**. Although the EPA had epidemiologic and laboratory data that linked more than sixty other airborne **toxins** with **cancer**, **birth defects**, or neurological disease, they remained unregulated. The regulatory process specified by Section 112 was expensive and conservative. It required the EPA to gather sufficient evidence to demonstrate that an airborne toxin was hazardous before it could act. Frequently, there was a lack of scientific information on the health effects of these toxins. There was also a strong potential for legal challenges by industry.

Records dating from 1987 indicated that between 1987 and 1989, over 2 billion pounds of toxic **chemicals** were released into the air each year. Furthermore, more toxic chemicals were released into the air than into any other medium (water or **soil**) during these three years. Environmentalists and their supporters in Congress argued that the 1970 program had not been successful. The issue of airborne toxins was a major **air pollution** problem that was not being adequately addressed by Section 112. For this reason, an improved program to regulate airborne toxins became a central component in the efforts to amend the Clean Air Act.

One of the major components in the 1990 Clean Air Act included provisions to regulate hazardous air pollutants. Title III of the law required the thousands of sources of airborne toxins in the country to use the best available technologies to control hazardous air pollutants (HAPs). The act listed 189 chemicals that are considered HAPs. This

effectively removed the power to designate hazardous air pollutants from the EPA. However, the legislation did provide a mechanism to designate other HAPs for regulation in the future. Since 2000, all major stationary sources, regardless of age, location, or size, have been required to meet emission standards for every HAP established by the EPA. Major sources of HAPs (those emitting at least 10 tons of one pollutant or 25 tons of a combination of pollutants, per year) are required to apply "maximum achievable control technology" (MACT) and are required to receive emission permits. An incentive-based provision of the 1990 Clean Air Act ensured that sources that voluntarily and permanently achieved HAP reductions of 90% (from 1987 levels) could postpone instillation of MACT for up to six years.

Under the revised law, the EPA was directed to focus on those HAPs and sources that are deemed the most dangerous. Further, the EPA was directed to devise strategies to control all sources of HAPs in urban areas. By the year 2000, the EPA was mandated to identify the 30 HAPs that posed the greatest threat to human health and to identify the sources generating 90% of these emissions. The EPA was also to devise a strategy to reduce HAP-related cancer risk by 75%. It ws estimated that these additional provisions would reduce hazardous air pollutants from industrial sources by 75–90%. The EPA has undertaken programs to comply with these directives. As of 2002, the EPA has not completed any of the mandates.

National Environmental Policy Act (1969)

The National Environmental Policy Act (NEPA) of 1969 was signed into law on January 1, 1970, launching a decade marked by passage of key environmental legislation and increased awareness of environmental problems. The act established the first comprehensive national policies and goals for the protection, maintenance, and use of the **environment**. The act also established the **Council on Environmental Quality** (CEQ) to oversee NEPA and advise the president on environmental issues.

Title I of NEPA declares that the federal government will use all practicable means and measures to create and maintain conditions under which people and **nature** can exist in productive harmony, while fulfilling the social and economic requirements of the American people. Included in this declaration are goals to attain the widest range of beneficial uses of the environment without undesirable consequences and to preserve culturally and aesthetically important features of the landscape. The declaration also commits each generation of Americans to stewardship of the environment for **future generations**.

To achieve the national environmental goals, the act directs all federal agencies to evaluate the impacts of major federal actions upon the environment. Before taking an action, each federal agency must prepare a statement describing (1) the environmental impact of the proposed action, (2) adverse environmental effects that cannot be avoided, (3) alternatives to the proposal, (4) short-term versus long-term impacts, and (5) any irreversible effects on resources that would result if the action were implemented. The act requires any federal, state, or local agency with jurisdiction over the impacted environment to take part in the decision-making process. The general public also is given opportunities to take part in the NEPA process through hearings and meetings, or by submitting written comments to agencies involved in a project.

Title II of NEPA created the CEQ, as part of the Executive Office of the President, to oversee implementation of NEPA and assist the president in preparing an annual environmental quality report. The CEQ existed until February 1993, when President Clinton abolished the council and established the White House Office on Environmental Policy, with broader powers to coordinate national environmental policy. The CEQ issued regulations in 1978 which implement NEPA and are binding on all federal agencies. The regulations (40 CFR Parts 1500-1508) cover procedures and administration of NEPA, including preparation of environmental assessments and environmental impact statements. Many federal agencies have established their own NEPA regulations, following CEQ regulations, but customized for the particular activities of the agencies. In addition, 11 states have passed state environmental policy acts, sometimes called "little NEPAs."

Federal agencies must incorporate the NEPA review process early in project planning. A complete environmental analysis can be very complex, involving potential effects on physical, chemical, biological and social factors of the proposed project and its alternatives. Various systematic meth-

ods have been developed to deal with the complexity of environmental analysis. There are three levels at which an action may be evaluated, depending on how large an impact it will have on the environment.

The first level is categorical exclusion which allows an undertaking to be exempt from detailed evaluation if it meets previously determined criteria designated as having no significant environmental impact. Some federal agencies have lists of actions which have been thus categorically excluded from evaluation under NEPA.

When an action cannot be excluded under the first level of analysis, the agency involved may prepare an environmental assessment to determine if the action will have a significant environment effect. An environmental assessment is a brief statement of the impacts of the action and alternatives. If the assessment determines there will not be significant environmental consequences, the agency issues a finding of no significant impact (FONSI). The finding may describe measures that will be taken to reduce potential impacts. An agency can skip the second level if it anticipates in advance that there will be significant impacts.

An action moves to the third level of analysis, an **environmental impact statement** (EIS), if the environmental assessment determines there will be significant environmental impacts. An EIS is a detailed evaluation of the action and alternatives, and it is used to make decisions on how to proceed with the action. An agency preparing an EIS must release a draft statement for comment and review by other agencies, local governments, and the general public. A final statement is released with modifications based on the results of the public review of the draft statement. When more than one agency is involved in an action, a lead agency is designated to coordinate the environmental analysis. An agency also may be called upon to cooperate in an environmental analysis if it has expertise in an area of concern. The CEQ regulations describe a process for settling disagreements which arise between agencies involved in an environmental analysis.

In addition to having to prepare their own environmental assessments and environmental impact statements, the **Environmental Protection Agency** (EPA) is involved in all NEPA review processes of other federal agencies, as mandated by Section 309 of the **Clean Air Act**. Section 309 was added to the Clean Air Act in 1970, after NEPA was passed and the EPA formed, with the purpose of ensuring independent reviews of all federal actions impacting the environment. As a result, the EPA reviews and comments on all federal environmental impact statements in draft and final form, on proposed environmental regulations and legislation, and on other proposed federal projects the EPA considers to have significant environmental impacts. The EPA's procedures for carrying out the Section 309 requirements are contained in the publication "Policies and Procedures for the Review of Federal Actions Impacting the Environment" (revised 1984). The EPA is also responsible for many of the administrative aspects of the EIS filing process. The NEPA review process includes an evaluation of a project's compliance with other environmental laws such as the Clean Air Act. Federal agencies often integrate NEPA reviews with review requirements of other environmental laws to expedite decision-making and reduce costs and effort.

NEPA requires that previously unquantified environmental amenities be given consideration in decision-making along with more technical considerations. That means that the environmental analysis can be a subjective process, guided by the values of the particular players in any given project. The act does not define what constitutes a major action or what is considered a significant effect on the environment. Some agencies have developed their own guidelines for what types of actions are considered major. Examples of major actions include construction projects such as highway expansion and creek channelization. However, major actions do not always involve construction. For example, legislative changes which may affect the environment may come under NEPA review. When an action will be controversial or clearly violate a pre-set environmental standard, it also may be categorized as a major action with significant impacts. Actions which will have less measurable effects, such as disrupting scenic beauty, must be categorized more subjectively. The courts are frequently used to settle disputes about whether actions require compliance with NEPA.

Although NEPA is targeted to federal agencies, its implementation has resulted in closer scrutiny of major environmental actions other than those sponsored by the government. Environmental analyses also are required for private developments which need federal **pollution control** permits such as water discharges, air emissions, waste disposal, and **wetlands** filling. *See also* Environmental impact assessment

National Estuary Program

The National Estuary Program (NEP) was established in 1987 when amendments to the **Clean Water Act** provided that the significant estuaries of the United States must be identified, and protected. According to the **National Oceanic and Atmospheric Administration**, (NOAA) in its publication *Where the Rivers Meet the Sea,* "An estuary occurs where saltwater from the sea meets and mixes with fresh water from the land." Estuaries are places where fresh and salt water mix. They are known as bays, harbors, sounds, or lagoons, as well. As much as 80% of the fish that are caught for food or for **recreation** depend on estuaries for all or part of their lives, according to the *National Association of Estuary Programs*. Because of their vital role in the impact of marine life, estuaries are often referred to as "cradles of the sea." The water bodies of the United States that play close to hearts of Americans and foreign visitors alike are estuaries—San Francisco Bay, **Chesapeake Bay**, Puget Sound, and Long Island Sound.

The extensive **ecosystem** that comprises all estuaries creates a similar balance of characteristics, as well as inherent problems. A continual force of tides and winds mix salt and fresh water constantly. Excessive **nutrient pollution** and loss of natural habitats—many due to human manipulation—can upset that mix and create an inhospitable **environment** for the living organisms that reside there. The estuary is not alone in its environmental home. The surrounding **wetlands**, rivers, and streams, as well as the land that courses through it and around it are all an integral piece of a whole that affects both humans and **wildlife** in their struggles for survival. The NOAA points out also that, "Estuaries are among the most biologically productive systems on earth. More than two-thirds of the fish and shellfish commercially harvested in coastal waters spend part or all their lives in estuaries."

As of 2002, the EPA had identified the key issues in managing estuaries, particularly those in the NEP, as well as the challenges they face in their survival. Common to each of the 28 areas named in the NEP are:

- overenrichment of nutrients—nitrogen and **phosphorus** are vital to a healthy aquatic system; in excess, they cause or add to fish disease, red or brown tide, algae blooms, and low dissolved oxygen
- pathogen contamination—viruses, bacteria, and **parasites** that indicate a health hazard to swimmers, surfers, divers, and seafood consumers
- toxic chemicals—metals, **polycyclic aromatic hydrocarbons** (PAHs) **polychlorinated biphenyls** (PCBs), **heavy metals**, and pesticides, all particularly threatening to humans who would consume any fish or seafood from the water body
- alteration of fresh water inflow
- **habitat** loss and degradation—the ecological balance of any estuary depends on the health of a habitat for survival
- decline in the fish and wildlife population.
- introduction of invasive species—either by intention or accident, such an addition can upset the balance of the system and create unexpected impacts economically, socially, and ecologically

As a voluntary, community based **watershed** program, the NEP has not only set as its goal to improve the quality of water in the estuaries. The program has sought to improve the entire ecological system—its chemical, physical, and biological properties, in addition to its economic, recreational, and aesthetic values. As of 2002, there were 102 estuaries in the United States. Only 28 of those have been designated as "nationally significant" and are therefore the focus of the entire effort of restoration and preservation. These 28 estuaries include 42% of the continental United States shoreline, with over half of the population living in the nation's coastal counties.

Since June 1995, the 28 nationally significant estuaries are Albemarle-Pimlico, NC; Barartaria-Terrebone, LA; Barnegat Bay, NJ; Buzzards Bay, MA; Casco Bay, ME; Charlotte Harbor, FL; Corpus Christi, TX; Delaware Estuary Program, DE, PA, NJ; Delaware Inland Bays, DE; Galveston Bay, TX; Indian River **Lagoon**, FL; Long Island Sound, NY and CT; Lower Columbia River, OR and WA; Maryland Coastal Bay, MD; Massachusetts Bay, MA; Mobile Bay, AL; Morro Bay, CA; Narragansett Bay, RI; New Hampshire Estuaries, NH; New York–New Jersey Harbor, NY and NJ; Peconic Bay, NY; Puget Sound, WA; San Francisco Bay, CA; San Juan Bay, Puerto Rico; Santa Monica Bay, CA; Sarasota Bay, FL; Tampa Bay, FL; and, Tillamook Bay, OR. The Chesapeake Bay in Maryland by itself is not specifically included in the NEP but is related to it. The Chesapeake Bay Program is a separate, federally-mandated program.

Economic factors as well as environmental concerns play a significant role in the maintenance of estuaries, primarily in estimating their worth. Each year, these particular estuaries account for over $7 billion in revenue from commercial and recreational fishing and related marine indus-

tries; $16 billion is generated by the attendant tourism and recreation activities.

The program as it has been established is a descendant of the early environmental programs of the 1970s and 1980s that sought to restore the **Great Lakes** and the Chesapeake Bay—all of which had become polluted to such an extent that concerns of whether the problems could be reversed were tantamount to the discussions and burgeoning activism that sought to fix them. When Cleveland's **Cuyahoga River** set fire in 1970 the laughter that was provoked publicly was only to hide a city's, and a nation's horror, that such an event had occurred.

Chesapeake Bay was about to meet a similarly dark fate with out of control pollution, unbridled industrial and private development, and a fishing industry that was dying. In 1983 the governors of Maryland, Virginia and Pennsylvania, the Mayor of Washington, D.C., and the EPA administrator signed the Chesapeake Bay Agreement committing their states and the District of Columbia to prepare plans for protecting and improving the **water quality** and living resources of the bay.

The implementation of the Chesapeake Bay Program, along with the 1965 **Water Resources** and Planning Act, the 1972 Federal **Water Pollution** Control Act, and the 1977 Clean Water Act laid the groundwork for the Comprehensive Conservation Management Plans (CCMP) for the estuaries that had been identified.

The process for developing the CCMP for the national estuaries involves four steps:

- building a management and decision-making framework
- scientifically characterizing existing resources and identifying priority problems
- developing both conventional and innovative solutions to identified problems
- implementing the management recommendations, with support from public and private sectors

Each local community has a particular stake in maintaining the estuary in its midst. The NEP is designed so that each community takes responsibility for managing it. Representatives from local, state, and federal governmental agencies join together to serve as managers of the estuaries. Local citizens, business leaders, educators, and researchers serve on a volunteer basis, too, and all groups work together to create their individual CCMPs. On the national level, the **Environmental Protection Agency** (EPA) administers the NEP—but the programs are carried out by the previously mentioned people. Nominations for determining significant estuaries are also handled by the EPA submitted to them by the governors of the states where the estuary is located. It is after an estuary has been named that the committees continue with their participation.

The Association of National Estuary Programs (ANEP) is a trade association that supports the 28 NEP estuaries, and provides for a joint effort in addressing the issues facing citizens and lawmakers. The ANEP has been successful in getting key legislation passed as in the instance of Senate Bill 835, signed by President Clinton; and responsible for committing federal dollars to restore a million acres of estuary habitat, and ensuring the continued survival of the National Estuary Program. *The Estuaries and Clean Waters Act of 2000* "authorizes a total of $275 million" until 2005 for matching funds for local restoration projects and also designates an additional $35 million per year until 2004 in support of the NEP. That bill also served to clear up the issue that NEP funds could be used to carry out existing, locally-crafted CCMPs for the 28 NEPs throughout the United States.

In celebration of the NEPs tenth anniversary in 1987, the EPA prepared a "Ten-year perspective" it has posted through it web site. It notes that, "A number of key lessons have been learned over the past 10 years. The NEP has demonstrated that community-based resource management achieves results. Although it takes time to see environmental changes such as improvements in water quality, progress is being made. In order to demonstrate improvements in an estuary, we have seen the importance of NEPs setting measurable environmental goals and indicators." Of the many local programs, EPA noted that, "the NEPs have created innovative management approaches to solve these [of the estuaries] common problems. They have employed alternative on-site **wastewater** treatment technologies to control **nitrogen**; established marina pump-out facilities; provided education and training for owners, installers, and pumpers of septic systems to reduce pathogens; promoted beneficial uses of dredged material to restore and create wetland habitat; installed fish passages to increase spawning; and, helped citizen volunteers remove invasive plant **species** from public areas."

There are a total of 130 estuaries in the United States—the question remains whether or not all of these should also become a part of the NEP. What improvements have been accomplished through the designated 28, however, can serve as focal points for improvements for those not named. **Restore America's Estuaries (RES)** is an organization dedicated to preserving the coastal integrity through the improvement of all estuaries, including those other then the 28 in the NEP. RES has prepared its document entitled, *A National Strategy to Restore Coastal and Estuarine Habitat* whose stated purpose it is to "provide a framework for restoring function to coastal and estuarine habitat." As with the ANEP, the work of RES includes professionals and citizens—scientists, community leaders, nongovernmental organizations, and governmental representatives from various agencies and lev-

els. **Communities Actively Restoring Estuaries (C.A.R.E.)** as of 2002, is scheduled to work in a three-year, $12 million in partnership with the NOAA's **Community-Based Restoration Program** to activate "on-the-ground" habitat restoration in 11 major estuaries throughout the United States. The program funds salt marsh restoration, oyster reef restoration, the installation of fishways, shoreline restoration, and other projects.

National forest

A national forest is forest land owned and administered by a national government. Mandates designating national forest ownership, administration and the distribution of benefits vary greatly around the world. Some nations (e.g. Canada) retain little or no national forest, delegating **public land** ownership to regional provinces or communities. Other nations (e.g. Albania and other formerly Communist States) retain all public forests as national forests. In many former colonies, national forest administration is patterned after that of the colonizing nation, and lands now comprising national forests were appropriated from **indigenous peoples**. In all cases, the term national forest refers to a type of *state* (i.e. government) property and must not be confused with forests that are owned as *common* property (i.e. private forest owned by a group) or *private* property. The precepts of modern national forests originated in early eighteenth century France and Germany where feudal lords set aside forests to preserve **hunting** grounds. National forest administration stems from this tradition of managing the forests for the direct benefit of central government authorities.

As in several nations in Southeast Asia, national forests in Indonesia comprise the vast majority of national territory, and colonial-style legal and organizational structures continue to dominate management. Forests are centrally administered by the State Forest Corporation with provinces given some authority over harvesting and marketing. Shared government and private party forestry successions are common. Indonesia derives a substantial portion of national income from timber production and has been charged with excluding the concerns of indigenous peoples from management decision.

In 1957 the government of Nepal nationalized all forested land, the majority of which was previously managed as community common property. This act resulted in the breakdown of community management systems and accelerated **deforestation** and forest degradation. The Forest Act of 1992 seeks to reverse these trends and divides national forests into five classes: community forests (managed by community user groups); leasehold forests (leased to private entities for timber production); government managed forests (retained by government for national purposes); protection forests (managed by government for environmental protection); and religious forests.

In the United States the term national forest refers to specific federal land units that are administered by the **U.S. Department of Agriculture Forest Service** (USDAFS). The USDAFS currently administers 156 national forests entailing 223 million acres and covering about one-tenth of the nation's land area. Establishment of these forests beginning in 1903 was largely a response to growing public fears of timber **famine**, wildfires, **flooding**, depleted **wildlife** populations, and damage to the beauty of the national landscape. National **forest management** is governed by federal law and edicts from the executive branch of government. The USDAFS is currently mandated to: 1) manage forests for multiple uses (wood, water, **recreation**, wildlife, and **wilderness** in perpetuity); 2) protect the habitats of **endangered species**; 3) impartially serve the public interest in choosing between management alternatives. National forests have been the focus of great conflict since the 1960s when the environmental movement began challenging USDAFS actions. Recent legislation, and numerous federal court decisions, have resulted in greater integration of public opinion into the USDAFS decision-making process.

National Forest Management Act (1976)

The National Forest Management Act (NFMA), passed in 1976, is the law that established the guidelines for the management of national forests. The act replaced the Organic Act of 1897, which had supplied such guidelines for the previous seventy-nine years. The impetus for this new bill was a court case related to **clear-cutting** on the Monongahela National Forest in West Virginia. Such clear-cutting had begun on this forest in the 1960s, and many environmental and **recreation** groups opposed it. When the **Forest Service** continued this management technique, the **Izaak Walton League** filed suit against the agency, claiming that clear-cutting violated the Organic Act on three counts: that only mature timber was to be harvested, that all timber cut had to be marked and designated, and that all timber cut had to be removed from the forest. The Court ruled in favor of the Izaak Walton League; clear-cutting did violate the Organic Act on each of these counts (*Izaak Walton League v. Butz*, (1973)). The judge issued an injunction against any cutting in West Virginia that violated the Organic Act. The Forest Service appealed, but lost, and the injunction was spread throughout the Fourth Circuit of the Court of Appeals (*Izaak Walton League v. Butz* (1975)). Injunctions based on similar cases were soon issued in Alaska and Texas. With timber harvesting on the national forests in chaos, the Forest Service and timber industry turned to Congress for new management authority.

Congressional action came quickly due to these court decisions. The debate centered around bills introduced by Senator Hubert Humphrey of Minnesota, more favorable to industry, and by Senator Jennings Randolph of West Virginia, supported by environmentalists. The final act was based primarily on the Humphrey bill. The act basically gave legislative approval to how the Forest Service had been managing the national forests. It granted the agency a great deal of administrative discretion to manage the forests based on the general philosophy of multiple use and sustained yield.

Five of the most contentious issues regarding national **forest management** were discussed in the law, but the fundamental issues were left unresolved. Clear-cutting is recognized as a legitimate management technique, and the Forest Service was given qualified discretion to determine when and how this approach would be used. **Species** diversity is to be considered in forest management, but the specifics are left to agency discretion. The Forest Service is directed to identify marginal lands and, based on agency discretion, to move away from timber management on these lands. Trees should be cut at a mature age when possible, but rotation age can be lessened if the agency deems it necessary. Finally, timber is to be harvested based on nondeclining even flow, which is a very conservative approach to sustained yield. Forest Service management decisions on these decisions have continued to stir debate. The NFMA also substantially amended the interdisciplinary national forest planning provisions of the Resources Planning Act of 1974. *See also* Biodiversity; Deforestation; Forest decline; Environmental law; Sustainable development

National Institute for the Environment

The National Institute for the Environment (NIE) was a proposed federal agency conceived in 1989 by a group of scientists, environmentalists, and policy analysts who were concerned that the nation's decision makers did not have adequate scientific information to make suitable environmental policies. They were also concerned that the existing federal environmental research and development activities were spread over many uncoordinated agencies, each with different missions and interests therefore preventing an integrated effort to resolve environmental problems. Led by Dr. Stephen Hubbell of Princeton University and Dr. Henry Howe of the University of Illinois, Chicago, the group developed a proposal to establish the NIE. This initiative to create the NIE was promoted by the National Council on Science and the Environment (NCSE), formerly called the Committee for the National Institute for the Environment (CNIE).

Formed in the late 1980s, the NCSE is a national nonprofit organization comprising 15 board members and

over 9,000 scientists, educators, business leaders, state and local government officials, environmental advocates, and other interested individuals from around the country whose goal it was to work with the United States Congress to establish the National Institute for the Environment (NIE).

The goal of the NIE was to have an independent, nonregulatory, federal institute similar to the National Institutes of Health that focuses on environmental problems. The NIE was to promote better communication between scientists and policy makers to help balance social, economic, and environmental goals. The NIE would also have concentrate activities in four integrated areas: identification and assessment of current knowledge of environmental problems of national interest through a Center for Environmental Assessment; the funding of peer-reviewed, interdisciplinary research to increase scientific understanding of these environmental problems through three research divisions; development of an electronic, on-line library (the National Library for the Environment) to disseminate environmental information; and support of education and training of scientists and other professionals interested in working on environmental issues. The NIE was to have been led by a President-appointed Board of Governors representing federal and non-federal scientists, state and local government, environmental organizations, citizen groups, academia, and industry.

Within the NIE, a Center for Environmental Assessment was to be established to perform evaluations on the current state of knowledge of particular environmental issues. Assessments would include a review of existing scientific information on an identified environmental problem, an assessment of policy decisions made based on existing information, and the identification of additional research needed to fill information gaps to improve the scientific basis for policy development.

The centerpiece of the NIE was the research it would sponsor. Experts in the natural sciences, engineering, economics, and the social sciences were to work cooperatively on complex environmental topics that could potentially require long-term investigations. Research funded by NIE was to be administered by three directors: a Director of **Environmental Resources**, a Director of Environmental Systems, and a Director of Environmental Sustainability. The Director of Environmental Resources would develop research programs to inventory **natural resources**, monitor and predict change to environmental systems, and develop tools for improved environmental assessment. The Director of Environmental Systems would focus on creating a research program to improve understanding of the functioning of environmental systems and human impact on these systems. For example, possible research programs could include an evaluation of the ecological and social effects of global **climate** change and research to distinguish between natural **ecosystem** variation and environmental change due to human activities. The director of Environmental Sustainability would concentrate on issues related to maintaining **environmental health** while utilizing resources in such a way to ensure their availability and viability in the future.

A key component of the NIE would be to provide information to decision makers, researchers, environmental managers, educators and other professionals, and the public at large. An electronic, on-line National Library for the Environment would be developed. The Committee for the National Institute for the Environment is in the process of establishing a prototype that can be accessed electronically. The prototype library will include research reports from the Congressional Research Service, an environmental encyclopedia, and peer-reviewed and nonpeer-reviewed research articles.

The NIE would support higher education training (i.e., education above the high school level) through research grants, fellowships, teacher training, and grants to develop environmental programs at colleges and universities. The NIE would also maintain a small in-house Center for Integrative Studies on the Environment that would invite visiting scholars to work with a core of scientific staff to evaluate emerging environmental issues on which NIE and other federal agencies need to focus.

The NIE proposal was endorsed by over 150 colleges and universities, scientific, professional, environmental, and business organizations, and state and local governments. Legislation to create the NIE was first introduced in 1989. The legislation was reintroduced in the 103rd Congress and again in 1995 during the 104th Congress by Representative Jim Saxton (R-NJ). The bill was co-sponsored by numerous Democratic and Republican members of Congress. The bill was referred to the House Committee on Science where in 1997 it awaited consideration by the Subcommittee on **Energy and the Environment**.

According to an NCSE update issued in January 2000, in 1999 they supsended the creation of the NIE and the "National Science Board approved an interim report recommending that the National Science Foundation implement most of the activities initially proposed for a National Institute for the Environment. In October 1999, [NCSE] announced its support for the full and effective implementation of this report and suspended its call for the creation of a National Institute for the Environment to work in support of the National Science Foundation initiative."

National Institute for Urban Wildlife

Since its founding in 1973 as the Urban **Wildlife** Research Center, this organization has promoted the preservation of wildlife in urban settings. In 1983, it became the National Institute for Urban Wildlife and continues to provide support to individuals and organizations involved in maintaining a place for wildlife in the expanding American cities and suburbs. The institute conducts research exploring the relationship between humans and wildlife in urban areas, publicizes methods of urban **wildlife management**, and raises public awareness of the value of wildlife in city settings. Its activities are divided into four programs: research, urban **conservation** education, technical services, and urban wildlife sanctuaries.

The research program provides specific information on the interplay between urban dwellers and wildlife. Developers, engineers, government agencies, industry, planners, students, and the general public use the research conducted by the institute. Some of the studies published by the institute have included *Planning for Wildlife in Cities and Suburbs*; *Urban Wetlands for Stormwater Control and Wildlife Enhancement*; *Planning for Urban Fishing and Waterfront Recreation*; *Highway-Wildlife Relationships: A State-of-the-Art Report*; and *An Annotated Bibliography on Planning and Management for Urban-Suburban Wildlife*.

Through its educational arm, the institute publishes numerous documents on the major issues of wildlife to professional environmentalists as well as to the general public. Among these publications is the quarterly *Urban Wildlife News*, the official publication of the organization. In addition to the newsletter, the institute publishes other resources such as the *Urban Wildlife Manager's Notebook*, the *Wildlife Habitat Conservation Teacher's PAC* series, and *A Guide to Urban Wildlife Management*.

Technical services are provided by the institute to urban planners, developers, land managers, state and federal non-game programs, and homeowners. Among the information and services offered are environmental assessments and impact statements, open space planning and management, recreational planning, experimental design, urban **wetlands** enhancement, data analysis, literature research, and expert testimony.

The urban wildlife sanctuaries program is designed to create a network of certified sanctuaries on public and private land across the United States. Landowners who dedicate their land to wildlife preservation and are certified by the institute receive support from the institute's wildlife biologists.

The institute's 1,000 members include organizations and individuals who are concerned with the preservation of wildlife in urban settings. Although there is no official volunteer program offered through the institute, guidance is available to members working in grassroots organizations.

National Institute of Environmental Health Sciences (Research Triangle Park, North Carolina)

The National Institute of Environmental Health Sciences (NIEHS) is one of 24 components of the National Institutes of Health (NIH), which is part of the **U.S. Department of Health and Human Services** (DHHS). The mission of NIEHS is to conduct research on environment-related diseases. The focus of research is on understanding how environmental factors, individual susceptibility, and age interrelate to cause human illness and on the development of methods to reduce these illnesses. NIEHS achieves its mission through biomedical research programs, prevention and intervention activities, and communication strategies that include training, education, technology transfer, and community outreach.

NIEHS was established as the Division of Environmental Health Sciences within NIH in 1966. In 1967, the Research Triangle Foundation in North Carolina presented the U.S. Surgeon General with 509 acres (206 ha) in the Research Triangle Park to serve as a site for NIEHS. In 1969, the Division of Environmental Health Sciences was raised to Institute status.

Research is conducted through both on-site resources and an extramural science program. The Division of Extramural Research and Training (DERT) supports a network of university-based environmental health science centers and also provides research and training grants and contracts for research and development. Through DERT, NIEHS supported the research of Dr. Mario J. Molina of the Massachusetts Institute of Technology (MIT), who was a co-recipient of the 1995 Nobel Prize in Chemistry for work showing the loss of the earth's protective **ozone** shield.

The purpose of the Division of Intramural Research (DIR) is to provide research to address the environmental components of many different diseases. Dr. Martin Rodbell, an NIEHS scientist in DIR, was a co-recipient of the Nobel Prize in Medicine for discoveries about the communication system that regulates cellular activity. DIR is organized into programs for Environmental Biology, Environmental Diseases and Medicine, and Environmental Toxicology. The

program for Environmental Biology includes the work of three laboratories. The Laboratory of Molecular Genetics studies the basic mechanisms of the mutational process, fundamental mechanisms of genomic **stability**, and the impact of environmental agents on the genetic apparatus. The Laboratory of Signal Induction studies the effects of environmental agents on physiological processes, and the Laboratory of Structural Biology studies environmentally associated diseases resulting from perturbations in biological.

The second DIR program, for Environmental Diseases and Medicine, includes three branches: **Epidemiology**, Biostatistics, and Comparative Medicine. The Epidemiology Branch studies the impacts of environmental toxicants on human health and reproduction using sensitive health endpoints, susceptible sub-groups, and highly exposed populations; four laboratories support this research. The Laboratory of Reproductive and Developmental Toxicology develops an understanding of the basic mechanisms underlying normal and abnormal development and reproduction. The Laboratory of Pulmonary Pathobiology studies the respiratory tract system biology at the cellular, biochemical, and molecular level in order to develop an understanding of pathogenic mechanisms involved in the onset of diseases of the airways. The Laboratory of Molecular Carcinogenesis studies the mechanisms of environmental carcinogenesis by identifying the target genes in the process and by defining how **chemicals** act on these genes to influence **cancer** development. The Laboratory of Environmental Carcinogenesis and Mutagenesis focuses on chemical, physical, and environmental causes of cancer and uses transgenic and computer models to distinguish carcinogens and the mechanisms by which they act.

The second branch of the program for Environmental Diseases and Medicine, Biostatistics, conducts research in biomathematics and population genetics and in design and analysis of laboratory animal toxicology and carcinogenicity studies to develop methodology for epidemiological and clinical studies, and to provide statistical and computational support to NIEHS scientists. The third branch, Comparative Medicine, provides services and collaborative support to NIEHS scientists in the areas of animal facilities management, animal procurement, health surveillance and disease diagnosis, clinical veterinary services, rodent breeding, technical and surgical assistance, and quality assurance support.

The third DIR program, that for Environmental Toxicology, uses the research conducted at three laboratories. Laboratory of Computational Biology and **Risk Analysis** conducts and coordinates research into the development and use of mechanistic data and models for characterizing and quantifying human health risks associated with exposure to environmental agents. It maintains a research program in computer-based mathematical **modeling**, ranging from modeling cellular and molecular levels to whole animals and focusing on describing and evaluating chemical structures, biological response mechanisms, and their perturbations by potentially hazardous environmental agents. It also develops and uses cellular and molecular markers to investigate the link between environmental exposures and toxicity. It provides approaches for the evaluation of human susceptibility factors that affect toxic environmental effects.

Two other laboratories aid DIR's Environmental Toxicology program. The Laboratory of Toxicology conducts studies to characterize chemical toxic effects, including immune, reproductive, genetic, respiratory, and nervous system toxicities. It studies interactions of chemicals and metabolites with subcellular macromolecules, and it develops methods for characterizing toxicity of chemicals and other agents. The Laboratory of Pharmacology and Chemistry studies the exposure and disposition of environmental chemicals; it studies the **enzyme** systems involved in the **metabolism** of environmental chemicals and drugs; and, it studies the mechanisms responsible for the toxic effects of xenobiotics and their metabolites, including photochemical and free radical mechanisms. The lab utilizes alternative model systems from comparative and marine biology to study the pharmacology and toxicology of chemicals and drugs, and it provides chemical support for NIEHS scientists, including the assessment of chemical purity, stability, and biotransformation.

NIEHS sponsors research on the effects of environmental impacts in several areas. Some research topics include birth and developmental defects and sterility; women's health issues, including breast cancer susceptibility and osteoporosis; and Alzheimer's and other neurologic disorders. NIEHS sponsors research on hazards to the poor due to likely exposure to **lead** paint, hazardous chemicals at work, air and **water pollution**, and **hazardous waste** sites in their communities; some researchers focus on **agricultural pollution**, including natural materials (e.g., grain dust) and **agricultural chemicals**, while other researchers study signal error, i.e., whether environmental chemicals can mimic hormonal growth factors and contribute to the development of cancer or reproductive disorders. Still other research investigates animal alternatives, to reduce the number of animals used in research, to refine the design of experiments to obtain more information at lower cost, and to replace animals with microbial and tissue cultures. Some research identifies biomarkers to measure the uptake and exposure to environmental **toxins**.

NIEHS is the headquarters for the National Toxicology Program (NTP), an interagency program within DHHS. The NTP was established in 1978 to coordinate toxicology research and testing activities within the Department of Health and Human Services, to provide information about potentially toxic chemicals to regulatory and research

agencies, and to strengthen the scientific basis of toxicology. The NTP coordinates toxicology activities of NIEHS, the National Institute for Occupational Safety and Health of the Centers for Disease Control (NIOSH/CDC), and the National Center for Toxicological Research of the **Food and Drug Administration** (NCTR/FDA). The director of NIEHS is also the director of the NTP. Primary research support within NIEHS for NTP is in the Environmental Toxicology Program.

The Superfund Basic Research Program (SBRP), in coordination with the U.S. **Environmental Protection Agency** (U.S. EPA), is also administered by NIEHS. The Superfund Amendments and Reauthorization Act (SARA) of 1986 established a university-based program of basic research within NIEHS. The SBRP receives funding from the U.S. EPA through an interagency agreement using Superfund Trust monies. The funding is used to study human health effects of hazardous substances in the **environment**, especially those found at uncontrolled, leaking waste disposal sites. The primary objectives of SBRP are to find methods, through basic research, to reduce the amount and toxicity of hazardous substances and to prevent adverse human health effects. The SARA legislation specifically mandates that the basic research program administered by NIEHS focus on: methods and technologies to detect hazardous substances in the environment; development of advanced techniques for the detection, assessment, and evaluation of the effects on human health of hazardous substances; basic biological, chemical, and physical methods to reduce the amount and toxicity of hazardous substances.

In support of these mandates, NIEHS supports projects in the areas of engineering, ecological, and hydrogeological research in conjunction with biomedically related components, thus encouraging collaborative efforts among researchers. Specific research areas included in the SBRP include health effects, exposure/risk assessment, **ecology**, fate and transport, **remediation**, **bioremediation**, analytical chemistry, biomarkers, epidemiology, metals, and waste site characterization.

NIEHS was also given responsibility for initiating a training grants program under SARA. The major objective of the NIEHS Worker Education and Training Program, initiated in 1987, is to prevent work-related harm by assisting the training of workers to know how to protect themselves and their communities from exposure to hazardous materials during hazardous waste operations, hazardous materials **transportation**, environmental restoration of **nuclear weapons** facilities, or chemical emergency response. Through this program, non-profit organizations with a demonstrated record of providing occupational safety and health education develop safety and health curriculum for workers involved in handling hazardous waste or in responding to emergency releases of hazardous materials. Information concerning this program is disseminated through the National Clearinghouse for Worker Safety and Health Training.

The SBRP, through an Interagency Agreement, provides additional training by support of the NIOSH Hazardous Substance Continuing Education Program (HST), initiated in 1988 for hazardous substance professionals, and the NIOSH Hazardous Substance Academic Training Program (HSAT), a graduate academic program initiated in 1993 allowing occupational safety and health professionals to specialize in the study of hazardous substances.

In coordination with the Department of Energy, NIEHS is overseeing the implementation of the Electric and Magnetic Fields (EMF) Research and Public Information Dissemination (RAPID) program, established by the 1992 **Energy Policy** Act. The EMF RAPID program is a five-year federally coordinated effort to conduct research on potential effects on biological systems of exposure to 60 Hz electric and magnetic fields produced by the generation, transmission, and use of electric energy and to evaluate developing technologies for characterizing and mitigating these fields. The program also involves collection, compilation, publication, and dissemination of information to the public concerning possible human effects of electric and magnetic fields; types and extent of human exposure to electrical and magnetic fields in various occupational and residential settings; technologies to measure and characterize electric and magnetic fields; and methods to assess and manage exposure to electric and magnetic fields.

The NIEHS Clearinghouse is an information service staffed with scientists who respond to questions concerning environmental health issues. Information on research is also provided through an NIEHS-sponsored journal, *Environmental Health Perspectives*.

National Institute for Occupational Safety and Health

The National Institute for Occupational Safety and Health (NIOSH) is a research institute created by the **Occupational Safety and Health Act** of 1970, and since 1973 it has been a division of the Centers for Disease Control (CDC). The purpose of NIOSH is to gather data documenting incidences of occupational disease, exposure, and injury in the United

States. After gathering and evaluating data, the agency develops "Criteria Documents" for specific hazards; in some cases the **Occupational Safety and Health Administration** (OSHA) has used these documents as the basis for specific legal standards to be followed by industry. NIOSH has developed databases which are available to other federal agencies, as well as state governments, academic researchers, industry, and private citizens. The organization also conducts seminars for those in the field of occupational safety and health, as well as for industry, labor, and other government agencies. NIOSH prepares various publications for sale to the public, and it provides a telephone hotline in its Cincinnati, Ohio office to answer inquiries.

In April of 1996, NIOSH and the Occupational Safety and Health Administration (OSH) commemorated their twenty-fifth anniversary in an event that was jointly sponsored by those two agencies and by the Smithsonian Institute. CDC Director David Satcher stated, "Thanks in large measure to NIOSH's efforts, the Nation has made dramatic advancements in recognizing that safe and healthful workplaces are an integral part of good public health, and that the tools we use to curb infectious diseases also work against occupational diseases—knowledge, timely intervention, and prevention."

National lakeshore

National lakeshores are part of a system of United States coastlines administered by the **National Park Service** and preserved for their scenic, recreational, and **habitat** resources. The national lakeshore system is an extension of the national seashores system established in the 1930s to preserve the nation's dwindling patches of publicly-owned coastline on the Atlantic, Pacific, and Gulf coasts. Since before 1930 the movement to preserve both seashores and lakeshores has been a conservationist response to the rapid privatization of coastlines by industrial interests and private home owners. In 1992 the United States had four designated National Lakeshores: Indiana **Dunes** on the southern tip of Lake Michigan, Sleeping Bear Dunes on Lake Michigan's eastern shore, and the Apostle Islands and Pictured Rocks, both on Lake Superior's southern shore.

Attention focused on disappearing **Great Lakes** shorelines, sometimes called the United States' "fourth coastline," as midwestern development pressures increased after World War II. During the 1950s lakeshore industrial sites became especially valuable with the impending opening of the **St. Lawrence Seaway**. The seaway, giving landlocked lake ports access to Atlantic trade from Europe and Asia, promised to boost midwestern industry considerably. Facing this threat to remaining wild lands, the **National Park** Service conducted a survey in 1957-58, attempting to identify and catalog the Great Lakes' remaining natural shoreline. The survey produced a list of 66 sites qualified for preservation as natural, scenic, or recreational areas. Of these, five sites were submitted to Congress in the spring of 1959.

The Indiana Dunes site was a spearhead for the movement to designate national lakeshores. Of all the proposed preserves, this one was immediately threatened in the 1950s and 1960s by northern Indiana's expanding steel industries. Residents of neighboring Gary were eager for jobs and industrial development, but conservationists and politicians of nearby Chicago argued that most of the lake was already developed and lobbied intensely for preservation. The Indiana Dunes provided a rare patch of undeveloped acreage that residents of nearby cities valued for **recreation**. Equally important, the dunes and their intradunal ponds, **grasslands**, and mixed deciduous forests provided habitat for animals and migratory birds, most of whose former range already held the industrial complexes of Gary and Chicago. In addition, the dunes harbored patches of relict boreal habitat left over from the last **ice age**. After years of debate, the Indiana Dunes and Great Sleeping Bear Dunes National Lakeshores were established in 1966, with the remaining two lakeshores designated four years later.

The other three national lakeshores are less threatened by industrial development than Indiana Dunes, but they preserve important scenic and historic resources. Sleeping Bear Dunes contains some of Michigan's sandy pine forests as well as **arid** land forbs, grasses, and sedges that are rare in the rest of the Midwest. Two prized aspects of this national lakeshore are its spectacular bluffs and active dunes, some standing hundreds of feet high along the edge of Lake Michigan.

Wisconsin's Apostle Islands, a chain of 22 glacier-scarred, rocky islands, bear evidence of perhaps 12,000 years of human habitation and activity. However most of the historic relics date from the nineteenth century, when loggers, miners, and sailors left their mark. In this area the coniferous boreal forest of Canada meets the deciduous Midwestern forests, producing an unusual mixture of sugar maple, hemlock, white cedar, and black spruce forests. Nearly 20 **species** of orchids find refuge in these islands. Pictured Rocks National Lakeshore preserves extensive historic navigation relics, including sunken ships, along with its scenic and recreational resources. *See also* Coniferous forest; Conservation; Ecosystem; Glaciation; National Parks and Conservation Association; Privatization movement; Wilderness

National Mining and Minerals Act (1970)

The Mining and Minerals Policy Act of 1970 was the first of a series of efforts by the United States Congress to address the seeming lack of a coordinated and comprehensive federal minerals policy. The act directed the Secretary of the Interior to follow a policy that encouraged the private mining sector in four ways: to develop a financially viable and stable domestic mining sector, to develop domestic mineral sources in an orderly manner, to conduct research to further "wise and efficient use" of these minerals, and to develop methods of mineral extraction and processing that would be as environmentally benign as possible. Given the broad and vague nature of these directives, it is difficult to determine what, if any, effect the law has had. For example, the U.S. Department of the Interior's report on the bill found that it did not provide the department any new authority. There was one clear directive included in the law: the Secretary of the Interior was to report to Congress annually on the mining

industry and to make any legislative recommendations to help the industry at that time.

Two additional general mining policy laws were passed within fifteen years of the Mining and Minerals Policy Act. The National Materials and Minerals Policy, Research and Development Act was passed in 1980. Like the 1970 Act, this law was an effort to develop a coordinated national minerals policy. But, like its predecessor, this law also had little effect due to its lack of specifics. The 1984 National Critical Materials Act underscored the concern among some in Congress that the United States had become vulnerable, due to foreign dependence, in the supply of such strategic defense and high technology minerals as cobalt and platinum group metals. This law was also filled with vague generalities, though it did create a three-person National Critical Materials Council and charged this Council with overseeing minerals policy. As with the prior two acts, the 1984 law has seemingly had little effect.

The growing concern for mineral policy in the 1970s and 1980s can be traced to three sources: administrative law and capacity, environmental concerns, and national security concerns. The federal government had little control over mining policy. On federal lands, mining policy had been essentially privatized by the 1872 Mining Law. Individuals or private firms could stake claims on public lands and remove the minerals; the government received no royalties and issued no permits. The mining policy regime was also fragmented. Three agencies had major roles in mining policy: the **Bureau of Land Management**, the Bureau of Mines, and the United States **Geological Survey**. Throughout the 1970s and 1980s, concern for the **environment** grew in the country, and a significant concern of environmentalists was mining operations, which often generated large amounts of **pollution** and had significant effects on the land. Hence, environmentalists successfully sought to restrict mining in certain areas and regulate the mining that continued. Partially in response to the reduced access and increased regulation, the mining industry and its supporters began to focus on the United States's foreign dependence on **strategic minerals**. They argued that more lands should be open to mining, and regulations should be relaxed. Despite the passage of these three laws, though, no significant change in federal mining policy has occurred. *See also* Environmental law; Environmental policy; Natural resources

National Ocean Service

see **National Oceanic and Atmospheric Administration (NOAA)**

National Oceanic and Atmospheric Administration

The National Oceanic and Atmospheric Administration (NOAA) is a multi-faceted agency of the United States government that concerns itself with a variety of challenges, from making five-day weather forecasts to protecting **sea turtles**. Under the U.S. Department of Commerce, NOAA is unusual because it functions not only as a service agency, providing weather reports, for example, but also as a regulatory and research agency. Many of its regulatory functions appear to overlap with those of the **Environmental Protection Agency** (EPA), and much of its research parallels that of National Aeronautics and Space Administration (NASA). NOAA's National Ocean Service, for example, assessed the damage to the Alaskan coast and **wildlife** from the disastrous oil spill of the ***Exxon Valdez***; NOAA also monitors the rate and speed of the earth's rotation.

Created in 1807 by President Thomas Jefferson as the National Ocean Service, its first duty was to survey the coasts to set up shipping lanes for trade routes in the United States. Later, its function as an air and sea chart-making agency, when known as the U.S. Coast and Geodetic Survey, was in high demand, especially during World Wars I and II.

In 1970, when the National Oceanic and Atmospheric Administration was instituted, it settled into five major service branches and a NOAA Corps. The Corps, called "the seventh and smallest uniformed service," consists of about 400 men and women trained to perform diverse duties, such as fly into the eye of a **hurricane** and make descents in ocean submersibles to do deep ocean research.

NOAA's five branches are as follows:

- National Weather Service (NWS): For a long time, NOAA was the U.S. Weather Bureau. NWS has provided daily weather forecasts for several decades by gathering data from manned weather forecast offices around the country. To perfect its capability, to increase **accuracy**, and to lengthen predictions for severe weather, NOAA is implementing a long-term program to modernize the National Weather Service by installing 1,000 automatic sensors in all the states. Already the Hydrometeorological Information Center can issue spring flood warnings from river forecast centers well in advance of their occurrence. Nexrad ("Next generation radar"), a new Doppler radar that can pick up severe weather 125 mi (201 km) away, predicts tornadoes with a 19-minute lead time, giving residents more time to find shelter.

- The Office of Oceanic and Atmospheric Research collects data from polar-orbiting and geostationary satellites. These not only provide televised weather pictures, but also monitor elements of **climate** change (such as **greenhouse gases** in the **stratosphere**). At NOAA's Environmental Research Labs, studies of the **ozone** layer are additionally being conducted jointly with NASA; NOAA and Japan have also joined forces to study the thermal vents 20,000 ft (6096 m) down in the Marianna Trench under the Pacific Ocean. NOAA funds university research through the National Sea Grant College Program and the National Undersea Research Program.
- The National Environmental Satellite, Data and Information Service (NESDIS), one of the world's largest banks of information on earth geophysics, solar activity, geomagnetic variations, and paleoclimates, stores data collected from NOAA's satellites and environmental research labs.
- The National Ocean Service still makes coastal charts for trade ships as well as for weekend sailors. But now it also assesses ocean and coastal **pollution**, protects **wetlands**, and is charged with creating and maintaining sanctuaries for various sea creatures including **whales** and living coral reefs.
- The National Marine Fisheries Service (NMFS) manages fisheries by overseeing coastal fish-breeding habitats, restoring **endangered species**, collecting abandoned drift nets, and trying to save turtles, **dolphins**, and whales that swallow sunken plastic balloons or get caught in plastic six-pack circles. The NMFS instituted the use of Turtle Excluder Devices (TEDs) on shrimp nets to keep turtles from being strangled.

NOAA also operates a rescue satellite, known as COSPAS-SARSAT (Satellite-Aided Search and Rescue). Stranded fishermen and sailors, whose boats are equipped with an Emergency Position Indicating Radio Beacon (EPIRB), send a signal to the satellite that relays it to a ground station which responds by sending a rescue vessel within hours of the initial signal.

Because NOAA is unusual in its functions as a regulatory, research, and service agency, it is often an easy target for budget-cutting. Underfunded during most of the 1980s and always dependent on Congressional funding, NOAA is currently struggling to streamline its duties in the face of rapid climate change and increased **marine pollution**.

National park

National parks are areas that have been legally set apart by national governments because they have cultural or **natural resources** which are deemed significant for the particular country. National parks are typically large areas that are mostly undisturbed by human occupation or exploitation. They are characterized by spectacular scenery, abundant **wildlife**, unique geologic features, or interesting cultural or historic sites.

National parks are managed to eliminate or minimize human disturbances, while allowing human visitation for recreational, educational, cultural, or inspirational purposes. Activities consistent with typical national park management include hiking, camping, picnicking, wildlife observation, and photography. Fishing is usually allowed, but **hunting** is often prohibited. In the United States, national parks are distinguished from national forests and other federal lands because timber harvesting, cattle grazing, and mining are, with a few exceptions, not permitted in national parks, whereas they are permitted on most other federal lands.

The United States was the first country to establish national parks. The Yosemite Grant of 1864 was the first act that formally set aside land by the federal government for "public use, resort and recreation." Twenty square miles (52 sq km) of land in the Yosemite valley and four square miles (10 sq km) of giant sequoia were put under the care of the State of California to be held "inalienable for all time." In 1872, President Ulysses S. Grant signed into law the establishment of **Yellowstone National Park**. Yellowstone differed from Yosemite in that it was to be managed and controlled by the federal government, not the state, and therefore has received the honor of being considered the first national park. Years later, Yosemite was turned over to the federal government for federal management also. Since 1916, national parks in the United States have been administered by the **National Park Service** an agency in the **U.S. Department of the Interior**.

The concept of national parks has caught on all over the world and continues to spread. Between the years 1972 and 1982 the number of national parks in the world increased

by 47% and the area encompassed in the parks increased 82%. Today over 1000 national parks can be found worldwide in more than 120 countries.

Many national parks in both developed and developing countries are facing threats, however. The most commonly reported threats are illegal removal of wildlife, destruction of vegetation, and increased **erosion**. Often there is a lack of personnel to deal with these threats. Management problems also arise because demand for use of park resources is increasing. Many of these uses are conflicting, and virtually all would have significant impacts on the resources that characterize the parks.

Although parks consist of natural resources, they are conceived, established, maintained, and often threatened by humans. It is necessary for a society to derive benefits from the parks to maintain public support for them. In light of the need for public support, merely putting a fence around the park and keeping people out is likely to fail in the long term. Paradoxically then, some development and use is necessary for **conservation** of the resources. Deciding on the appropriate amounts and kind of uses compatible with the resources is the key to successful park management.

During the summer of 1962 the first World Conference on National Parks was held in Seattle, Washington. This historic conference and subsequent ones have given people of many nations a forum to discuss threats facing their parks and strategies for meeting the demand for conflicting uses. Only through such international dialogue and continued diligence will these treasures we call national parks be saved for **future generations**.

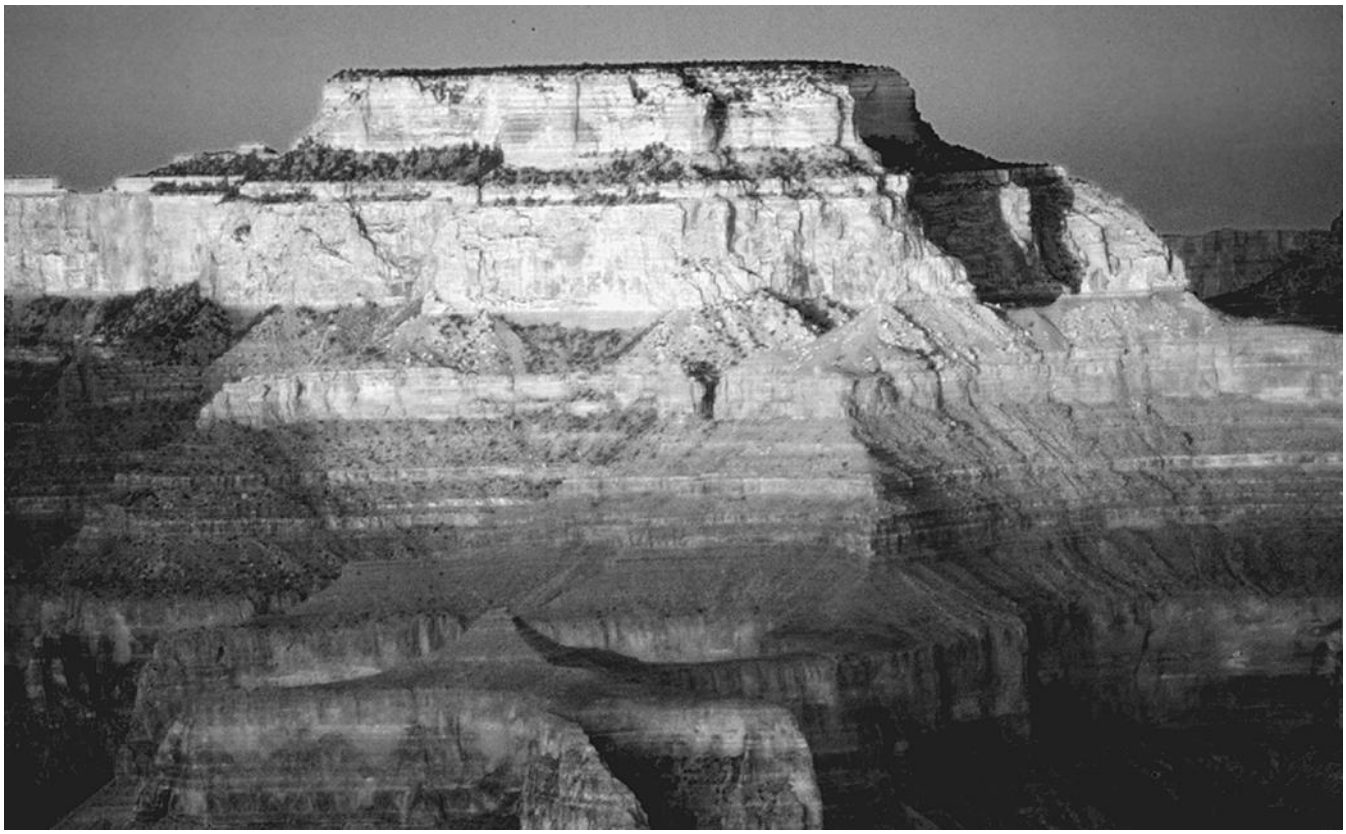
National Park Service

The **National Park** Service, an agency in the **U.S. Department of the Interior**, was established by the National Park Service Act of 1916 making it the first such agency in the world. Its mission as stated in the Act is: "to conserve the scenery and the natural and historic objects and the wild life therein and to provide for the enjoyment of the same in such a manner and by such means as will leave them unimpaired for the enjoyment of future generations."



The mission has not changed over the years but the ambiguous wording of the act has sparked much debate over what the primary use of a national park should be. Some people feel the parks should be commercially developed in order to best "provide for the enjoyment" of the resources, whereas others think the highest priority should be preserving the resources in an "unimpaired" state for **future generations**. These conflicting views have existed ever since the agency was established, and the debate will likely continue. The dual mandate of providing enjoyment from the resources and leaving them unchanged has been called the "preservation/use paradox." Striking the balance between use and preservation is still at the forefront of current national park policy issues.

National parks existed in the United States prior to the establishment of the National Park Service. The Yosemite Grant of 1864 was the first act that formally set aside land by the federal government for "public use, resort and recreation." Twenty square miles (52 km^2) of land in the Yosemite valley and 4 mi^2 (10 km^2) of giant sequoia were put under the care of the State of California by President Abraham Lincoln. This land was to be held "inalienable for all time." In 1872, President Ulysses S. Grant signed into law the establishment of **Yellowstone National Park**. Yellowstone differed from Yosemite in that it was to be managed and controlled by the federal government, not the state, and therefore has received the honor of being considered the first national park. Years later, Yosemite was also turned over to the federal government for management.

Originally no money had been set aside for the protection and care of the national parks. The parks suffered from illegal timber harvesting, grazing, **poaching**, and vandalism. The U.S. Cavalry was sent in to protect the lands and did so until 1916 when the National Park Service was formed.

Horace Albright was named Assistant for Parks in 1913 by the Secretary of Interior Franklin Lane. Albright, in turn, recruited self-made millionaire and **nature** lover Stephen Mather to help him establish an agency to manage the parks. All the parks thus far had been created through separate acts of Congress with no unified guidelines to manage and control them. Bills to form an agency to oversee the parks had been introduced to Congress, but none had yet passed. Through the intensive lobbying efforts of Albright, Mather, and others, the National Park Service was formed in 1916. Upon its creation the National Park Service took over the management of 14 national parks and 21 national monuments. Mather was the named the agency's first Director and Albright became his assistant. Later Albright would become the second Director of the National Park Service.

Albright and Mather believed that if the park system was to successfully defend itself from attacks by individuals with utilitarian philosophies (i.e., those believing timber cutting, grazing, and mining should be allowed on federal lands) it would have to have a strong base of public support. They

Grand Canyon National Park in Arizona. (Photograph by Robert J. Huffman. Fieldmark Publications. Reproduced by permission.)

emphasized a tourism effort to "See America First" and embarked on a policy of development and expansion to include tennis courts, **golf courses**, and swimming pools. As the **automobile** became popular they encouraged visitation by car and tried to make the parks easily accessible. Through their efforts park use soared.

Although public support was strong, lands still had to be deemed worthless for agriculture or economic development to be set aside as parks by Congress. Therefore, parks typically were high altitude with steep rocky terrain. Also, because they were still being justified and preserved as tourist destinations, only those areas of spectacular scenery were included within the park boundaries. This has resulted in many management problems, as today park managers attempt to look after park resources that are a part of ecosystems which extend beyond the park boundaries.

The number of visitors to the parks increased so greatly that by the 1920s the limited facilities could no longer keep up with the growing demand. Overcrowding and **pollution** were becoming problems. Conservationists complained that tourism was given priority over preservation and that the parks were being degraded. Lodges and other amenities continued to be added to the parks to handle the increased visitation.

Until the establishment of **Everglades** National Park in 1934, all of the national parks had been designated from land that was already under federal government control. The Everglades was the first park taken from annexed private land. It was also the first park that was not preserved for its spectacular scenery. Rather it was primarily established to preserve its fragile **ecosystem**, especially its colorful and conspicuous **wildlife**. Shortly thereafter, the Great Smoky Mountain and Shenandoah National Parks were established. These were developed from private lands that were purchased using donations from private citizens, including John D. Rockefeller.

With the growing environmental awareness of the 1970s increased public scrutiny was focused on the balance between providing an enjoyable experience for visitors while preserving the park resources. The National Park Service looked for ways to accommodate the increasing numbers of visitors while minimizing the impacts to the **environment**. For example, to cut down on pollution and congestion, shuttle buses now take visitors into the Yosemite, Grand

Canyon, and Denali national parks. The National Park Service continues to seek creative ways to simultaneously achieve their dual missions of use and preservation.

The National Park Service administers 386 sites covering 80 million acres (32.4 million ha) in 49 states. Fifty of these sites are national parks, sometimes referred to as the "crown jewels" of the United States. The largest of the parks is Wrangell-St. Elias covering 13.2 million acres (5.3 million ha) in Alaska. In 1989 use at National Park Service facilities was measured at 114 million visitor days. The most visited national park is Great Smoky Mountain National Park.

In addition to the national parks, the National Park Service also administers 79 National Monuments, 69 National Historic Sites, and 29 National Historic Parks. They manage sites in 22 different categories including wild and scenic rivers, seashores, lakeshores, scenic trails, parkways, preserves, and even the White House. Each of the sites are placed into one of these categories based on such attributes as size, level of development, and significance. They are managed under policies appropriate for that type of site. For example, a national preserve is typically set aside to protect a particular resource. **Hunting**, fishing, mining, or extraction of fuels can be allowed on the preserve so long as it does not threaten the specific resource being preserved.

Each year millions of people from around the world come to the National Parks to recreate, to learn, and to be inspired in these wondrous places. Truly, the National Park Service is the caretaker of America's "crown jewels."

National Parks and Conservation Association

The National Parks Conservation Association (NPCA) was founded in 1919 for the defense, promotion, and improvement of the United States' **national park** system and the education of the general public regarding national parks. Throughout its history, the NPCA has worked toward a three-fold goal: to save the parks from exploitation, **pollution**, and degradation of their **natural resources**; to facilitate easy access to the national parks for all Americans; and to preserve the great variety of **wildlife** found within the boundaries of the parks.

With a membership of 280,000—including both individuals and organizations—the NPCA boasts considerable political influence and is particularly effective in organizing ground swell support. Members are kept informed of political, environmental, and other issues through *National Parks*, the official NPCA publication. The magazine also contains articles of interest on state parks, international public lands, and matters of general environmental importance.

For more than 70 years, the NPCA has helped increase the holdings of the National Park System by lobbying for the expansion of existing grounds and for the establishment of new parks. Through the National Park Trust Fund, the NPCA has acquired and donated land to the National Park System. It has labored to protect national parks from overdevelopment and encroaching **urban sprawl** and has participated in studies to analyze and minimize the impact of visitor traffic.

Other support programs sponsored by the NPCA include fund raisers such as the March for Parks program, independent studies of resource management in national parks, and efforts to protect and revitalize populations of wild animals within the parks. Working in conjunction with other conservation groups, the NPCA has dealt with such wide ranging environmental issues as **air pollution**, **acid rain**, **water pollution**, **endangered species**, and damage to coastal areas.

Through its bimonthly magazine, *National Parks*, the NPCA helps coordinate grassroots activities such as the Park Watchers Program, a network of concerned local parties who keep track of potential threats to the Park System, and the Contact System which alerts members to make their views known to public officials on issues concerning the **environment**. Services to its members include special tours of national parks, general information about environmental issues and their impact on the Park System, and periodic legislative updates and action alerts.

A second bimonthly publication, *Exchanges*, is directed to those who participate in NPCA volunteer programs. These volunteers serve in a variety of capacities, including public relations, trip coordination, event planning, and fundraising.

The NPCA also has significant political influence, supporting such proposals as the American Heritage Trust Act, which would "protect our historic and natural heritage" with funding provided by royalties from offshore **oil drilling**. Internships are offered by the NPCA to college students and graduates who want to work in the legislative process.

National pollutant discharge elimination system

The National Pollutant **Discharge** Elimination System (NPDES) seeks to end the discharge of all types of industrial, municipal, and agricultural waste from point sources into American waters. These point sources include industrial facilities and publicly owned treatment works (POTWs), as well as **runoff** from urban areas.

The NPDES was established by the Federal **Water Pollution** Control Act Amendments of 1972 and was expanded under the **Water Quality** Act of 1987. Most NPDES programs are administered by the states, under the direction of the Office of **Wastewater** Management of the U. S. **Environmental Protection Agency** (EPA).

Nationwide more than 400,000 facilities are required to obtain NPDES permits. NPDES permits usually license a facility to discharge a given amount of a pollutant under specific conditions, although permits also are granted for other types of waste disposal. Permits are required only for facilities that discharge directly into bodies of water. The NPDES National Pretreatment Program regulates indirect discharges, such as discharges to POTWs. Although the NPDES encompasses all of the nation's surface waters, including **wetlands** and seasonal streams, discharges into ground water that is not connected to surface water are not regulated unless required by the state. Individual permits are issued to a single facility for a maximum of five years. General permits license multiple facilities that have similar types of discharge within a specific geographical area. Most agricultural facilities, with the exception of concentrated-animal-feeding facilities, are exempt from NPDES regulations.

NPDES permits require that discharges be treated using the best technology available. If these technology-based standards do not protect the water, water-quality-based standards must be met instead. Permits may contain both technology-based limits, such as a nationwide limit on total suspended solids in a discharge, and water-quality-based limits, such as ammonia limitations based on aquatic toxicity. Permits issued by the EPA must meet state water-quality standards and local discharge limits. Permits include monitoring and reporting requirements and draft permits are open for public comment.

The NPDES initially focused on controlling the discharge of conventional pollutants such as suspended solids, oil and grease, and disease-causing organisms. By 1989 facilities were required to meet "Best **Conventional Pollutant** Control Technology" (BCT) limits, as well as "Best Available Technology Economically Achievable" (BAT) limits for the discharge of toxic and non-conventional pollutants. Toxic and priority pollutants include 126 metals, organic substances, and pollutant classes. Non-conventional pollutants include **nitrogen**, **phosphorus**, **chlorine**, and ammonia, as well as parameters such as whole **effluent** toxicity. BAT standards require facilities to utilize the best control and treatment methods that are achievable. Unlike earlier NPDES standards, the benefits do not have to be weighed against the costs of control and treatment.

NPDES permits typically require POTWs to provide physical separation and settling of wastes, biological treatment, and disinfection. The NPDES also regulates **sludge** from POTWs, as well as municipal separate **storm sewer** systems and combined sewer overflow systems. The latter discharge untreated effluent during storms. Polluted storm water discharges include runoff from land, streets, parking lots, and building roofs. Industrial storm-water discharges must meet both water-quality-based standards and the storm-water equivalents of BCT and BAT standards. By March 2003 NPDES storm water permits will be required for construction sites of at least one acre, as well as some smaller sites.

The NPDES has significantly reduced the discharge of pollutants into American waterways and has brought about major improvements in the quality of the nation's **water resources**. In 1972 only one-third of these waters were safe for swimming and fishing compared with two-thirds in 2001. Wetlands loss has been reduced from 460,000 acres annually to 70–90,000 acres per year. **Soil erosion** from agricultural runoff has been reduced by one billion tons annually. Nitrogen and phosphorous levels in waterways have decreased. Modern wastewater treatment facilities now serve 173 million people, compared to only 85 million in 1972. As of 2001, more than 50 categories of industry and hundreds of thousands of businesses, as well as more than 16,000 municipal **sewage treatment** systems, were in compliance with the NPDES standards.

However the remaining sources of water **pollution** are more difficult to regulate. The EPA estimates that over 20,000 river sections, lakes, and estuaries, including about 300,000 miles of shoreline, are polluted. The vast majority of the American population lives within 10 miles of these waters. The millions of smaller sources of pollution are varied and less amenable to available technological solutions. These include hundreds of thousands of storm-water sources and about 450,000 animal-feeding operations. Therefore the NPDES is focusing more on the pollution problems of individual watersheds, developing total maximum daily loads,

or pollution budgets, for up to 40,000 bodies of water and rivers segments.

National Priorities List

The National Priorities List, or NPL, is a list compiled by the **Environmental Protection Agency** (EPA) as a part of the Superfund program under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA). CERCLA was enacted by Congress on December 11, 1980. This law levied a tax on the chemical and **petroleum** industries and gave the Federal government broad authority to respond directly to actual or threatened releases of hazardous substances. $1.6 billion was collected in the five years between 1980 and 1985. The tax money was placed in a trust fund for cleaning up abandoned or uncontrolled **hazardous waste** sites. CERCLA was amended by the Superfund Amendments and Reauthorization Act (SARA) on October 17, 1986.

CERCLA requires the EPA to identify hazardous waste sites on an annual basis throughout the United States. The law allows for two types of response: short-term removal of hazardous materials in emergency situations; and long-term remedial response actions. Long-term response actions can be conducted only at sites placed on the National Priorities List (NPL) by the EPA.

After in-depth testing and studies, the EPA places sites on the NPL in order of severity of contamination. Contamination is measured by the **Hazard Ranking System** (HRS), which yields a numerical score calculated on the basis of the site's risk factors. Risk factors are grouped into three categories: the site's potential for releasing hazardous substances into the **environment**; the amount and toxicity of the waste materials; and the number of people or sensitive environments affected by the hazardous materials. The HRS evaluates four possible pathways of contamination: ground water; surface water; **soil** exposure; and air **migration**.

HRS scores range between 0 and 100. Sites that score above 28.5 qualify for listing on the NPL. A site may also be listed if the **Agency for Toxic Substances and Disease Registry** (ATSDR) issues a health advisory for the site. In addition, each state or territory of the United States is allowed to place one top-priority site on the NPL without regard to its HRS score. The proposal is then published in the *Federal Register* . At this point, the public has an opportunity to comment in writing on the site's addition to the National Priorities List. As of May 29, 2002, 812 sites on the NPL were classified as having construction completed; 1221 sites remained on the NPL, with 74 new sites proposed for addition to the list.

The EPA administers the Superfund program in cooperation with individual states and Native American tribal governments. The Office of Emergency and Remedial Response (OERR) oversees management of the program. *See also* Hazardous waste site remediation; Hazardous waste siting; Superfund Amendments and Reauthorization Act

National Recycling Coalition

Founded in 1978, the National **Recycling** Coalition (NRC) is a non-profit organization comprised of concerned individuals and environmental, labor, and business organizations who wish to promote the recovery and **reuse** of materials and energy. Believing that recycling is vital to the nation's

well-being, NRC encourages collection, the development of more processing venues, and the purchase and promotion of recycled materials.

Originally formed by a small group of recycling professionals to convince others that recycling provides many benefits to America's economy, NRC has since grown to 4,500 members. They participate in several different projects, including the Peer Match Program—in which NRC gives technical advice and direct assistance in recycling—and technical councils such as the Rural Recycling Council and the Minority Council. The most prominent of these councils is the Recycling Advisory Council (RAC)

The Coalition established the RAC in 1989 to build consensus on recycling issues. Partially funded by the U.S. **Environmental Protection Agency** (EPA), the mission of the RAC is to "examine the current status of recycling in the United States with the aim of recommending consensus public policies and private initiatives to increase recycling, consistent with the protection of public health and the environment." The NRC Board of Directors selects members of the RAC from among high-ranking environmental and public interest groups, recycling professionals, and business and industry. The RAC examines information on a specific recycling topic and then issues recommendations; both public and private organizations recognize the standards the RAC sets. Some topics about which the Council has made decisions include the definition of recycling; solid **waste management** costs; and policies and initiatives to promote the recycling of paper and **plastics**.

One of the most productive campaigns of the NRC has been the "Buy Recycled Business Alliance." Twenty-five major American businesses in cooperation with NRC have agreed to increase the number of their products and packages made with recycled materials. In conjunction with the Alliance, NRC launched the "Buy Recycled" campaign. Aimed at consumers, it promotes a market for recycled products by encouraging the patronage of companies that sell such products. NRC maintains that first, one must request and buy recycled products, then one must ask governments and businesses to buy recycled material, and third, one should help develop a lasting system for procuring recyclable material.

NRC sponsors an annual conference, the National Recycling Congress and Exposition. Regarded as the nation's most significant recycling event, this membership meeting exhibits the latest innovations in recycling and allows networking within the recycling industry. NRC also publishes a quarterly newsletter and the *National Policy on Recycling and Policy Resolutions*, thereby keeping members and the concerned public abreast of recycling matters.

National Research Council

The National Research Council (NRC) was organized by the **National Academy of Sciences** (NAS) in 1916 to connect the broad community of science and technology with the goals of the NAS, i.e., advancing the state of knowledge and advising the federal government. The NRC has become the principal agency of both the NAS and the National Academy of Engineering (NAE) in providing services to the government, the public, and the scientific and engineering communities. The NRC is administered by both Academies and the Institute of Medicine.

During the early years of World War I, there was concern about the lack of American preparedness if the United States should enter the war. The NAS had been active during the Civil War and for some years after the end of the war, but had become inactive during the latter part of the nineteenth century and into the first decade of the twentieth century. In 1915, George Ellery Hale, an astrophysicist and member of the NAS since 1902, advocated to the NAS president the offering of the services of the NAS to the U.S. Government in case of entry in the war. In April of 1916, Hale introduced a resolution to the NAS, which passed unanimously, that stated:

"That the President of the Academy be requested to inform the President of the United States that in the event of a break in diplomatic relations with any other country the academy desires to place itself at the disposal of the Government for any service within its scope."

President Woodrow Wilson agreed to the proposal, and a Committee for the Organization of the Scientific Resources of the Country for National Service was appointed. Members of the committee included some of the leading scientists of the time: physicist Robert A. Millikan, biologist Edwin G. Conklin, medical laboratory director Simon Flexner, and physical chemist Arthur A. Noyes. In June of 1916 the committee called for:

"A National Research Council, the purpose of which shall be to bring into cooperation government, educational, industrial, and other research organizations with the object of encouraging the investigation of natural phenomena, and increased use of scientific research in the development of American industries, the employment of scientific methods in strengthening the national defense, and such other applications of science as will promote the national security and welfare."

The plan was approved by the NAS and by President Wilson. The NRC was organized in September, 1916, with Hale as the first chairman. Members represented the government, various branches of the military, universities, and private research laboratories. Members were grouped into Divisions, which were organized according to disciplines or functions. Smaller units within the Divisions worked on specific projects and studies.

Although organized to meet a specific emergency, the NRC, due to its valuable wartime service, was made a permanent organization by an executive order of President Wilson in 1918.

Presently, the activities of the NRC are supervised by Major Program Units. The Major Program Units may conduct projects on the their own, but more frequently supervise projects organized under numerous subsidiary standing boards and committees. These boards and committees, which provide independent advice to the government, are comprising experts who serve without compensation. They provide draft reports on issues of concern and subject the draft reports to rigorous review before release to ensure quality and integrity. The composition and balance of the study committees are carefully monitored to avoid potential conflict of interest and bias. Major Program Units include: Policy Division; Center for Sciences, Mathematics, and Engineering Education, Commission on Behavioral and Social Sciences and Education; Commission on Engineering and Technical Systems; Commission on Geosciences, **Environment**, and Resources; Commission on Life Sciences; Commission on Physical Sciences, Mathematics, and Applications; Office of International Affairs, Office of Scientific and Engineering Personnel; Board on Agriculture; and **Transportation** Research Board.

The NRC also provides library services to the staffs and committee members of the NAS, NAE, and the Institute of Medicine as well as to the NRC.

National seashore

The **National Park Service**, under the **U.S. Department of the Interior**, manages ten tracts of coastal land known as national seashores. Over 435 miles (700 km) of Atlantic, Gulf, and Pacific coastline, including over 592,800 acres (240,000 hectares) of beaches, **dunes**, sea cliffs, maritime forests, fresh ponds, marshes, and estuaries comprise the National Seashore System.

Protection of the sensitive natural habitats is only one of the objectives of the National Seashores System that the Park Service has established. These areas are also lightly developed for recreational purposes, including roads, administrative buildings, and some commercial businesses. In fact, until recently it was stipulated that public access must be provided to these areas. A third objective is to combat coastal **erosion**, as beaches and dunes are important as buffers to coastal storms.

The need to preserve coastal areas in their natural states was recognized as long ago as 1934, when the Park Service surveyed the Gulf and Atlantic coasts and identified 12 areas deserving of federal protection. The first of these to be authorized was Cape Hatteras National Seashore, a narrow strip of **barrier island** on the North Carolina outer banks. Acquiring the land, however, remained a problem until after World War II, when the Mellon Foundation matched state contributions and purchased the first of what is now over 100 mi (160 km) of beaches, dunes, marsh, and maritime forest.

In 1961, Cape Cod National Seashore in Massachusetts was the second area to be so designated. Protecting beach and dune areas of biological and geologically significance, this site was acquired with legislation that set the standard for future Park Service acquisitions. The "Cape Cod Formula" is the model for current regulation and purchase of private improved lands by the Park Service.

Five more sites were authorized between 1962 and 1966, including Fire Island on Long Island, New York, and Point Reyes National Seashore, the only national seashore on the west coast. Assateague Island, on the eastern shore of Maryland and Virginia, was deemed too developed to become a protected area but a nor'easter storm in March 1962 destroyed or seriously damaged nearly all of the development. By 1965, about 31 mi (50 km) of shoreline were purchased and became part of the National Seashore System.

In the 1970s, the final three national seashores were authorized. Gulf Islands is a non-continuous collection of estuarine, barrier island, and marsh habitats in Mississippi and Florida. It also includes an historic Spanish fort. Cumberland Island, Georgia, is the most "natural" of the ten national sea shores and is completely undeveloped with the only access being a public ferry from the mainland. The other National Seashores are Padre Island, in Texas; Cape Lookout, in North Carolina; and the newest national seashore, Florida's Cape Canaveral.

The National Historic Preservation Act (passed in 1966), the **Coastal Zone Management Act** (1972), and the National Seashore Act (1976) have been written to ensure that not all natural coastal areas fall to development. Public

recognition and subsequent congressional action have saved these few areas that are important as fish and shellfish spawning and nursery areas, bird and sea turtle nesting grounds, and refuges for threatened vegetation and **wildlife**. *See also* Wetlands

National Wildlife Federation

With over five million members or supporters, the National **Wildlife** Federation (NWF) is the country's largest and one of its most influential **conservation** organizations. The NWF has worked since 1936 to "promote wise use of the nation's wildlife and natural resources," and their primary goal is "to educate citizens about the need for sustainable use and proper management of our natural resources."

NWF sponsors National Wildlife Week, held during Earth Action Month, and it distributes over 600,000 education kits to more than 20 million elementary school students. NWF also operates the Institute for Wildlife Research, which concentrates on such creatures as bears, wild cats, and birds of prey. Their Backyard Wildlife **Habitat** Program distributes information and encourages homeowners to set up their own refuges for wild animals by providing food, water, and shelter, and by planting or preserving trees and shrubs and building backyard ponds. The program has certified more than 6,000 backyard habitats nationwide, and the group maintains a model backyard habitat at Laurel Ridge Conservation Center in Vienna, Virginia.

The National Wildlife Federation also sponsors a variety of nature-oriented meetings and programs. These include workshops and training sessions for grassroots leaders, children's wildlife camps and Teen Adventure Programs at facilities in North Carolina and Colorado, and NatureQuest, a leadership training program for young people. The organization also offers conservation internships, allowing young people to work with their professional staff; outdoor vacations for adults and families; symposiums and lectures on urban wildlife and gardening at the Laurel Ridge Conservation Center; and the National Conservation Achievement Awards, recognizing outstanding work in the field. Other NWF activities include co-presenting the PBS series "Conserving America," producing a biweekly column called "The Backyard Naturalist," which appears in 7,000 publications nationwide, and publishing books on wildlife for adults and children.

NWF's magazines have a combined circulation of 1.7 million, and include the bimonthly publications *National Wildlife* and *International Wildlife* for adults, *Ranger Rick* for elementary school children, and *Your Big Backyard* for preschoolers. NWF also publishes *The Conservation Directory*, a comprehensive listing of about 2,000 regional, national, and international conservation groups, agencies, and officials, and *NatureScope*, a science and **nature** school activity series used by over 30,000 teachers of elementary and middle school students.

Each year, NWF issues its Environmental Quality Index, assessing the status of air, water, wildlife, and other **natural resources**, as well as the quality of life in America. It also coordinates a nationwide **bald eagle** count each year and distributes millions of its famous wildlife stamps. NWF has been involved in a wide range of political campaigns. They have challenged government **strip mining** and timber cutting programs, worked to upgrade the **Environmental Protection Agency** (EPA) to cabinet-level status, helped strengthen enforcement of the **Safe Drinking Water Act**, and created the Corporate Conservation Council to encourage dialogue with industry on conservation issues.

The National Wildlife Federation differs from many other conservation groups in that the organization, and especially its state affiliates, strongly advocates **hunting and trapping**, emphasizing consumptive management of wildlife over pure preservation and protection. This has, at times, placed NWF at odds with other conservation groups, particularly during the 1979–80 fight over the Alaska lands legislation. In this battle, the federation strongly opposed protectionist bills supported by the general conservation community and fought instead for legislation supported by oil and gas interests, as well as **hunting** supporters. However, under the recent leadership of Jay D. Hair, the NWF has become somewhat less anti-preservationist (although most of its affiliates remain in that mold). The group is now considered a stronger advocate for environmental causes, even some controversial causes it would not have supported in earlier years.

National wildlife refuge

The United States began establishing **wildlife** refuges under **Theodore Roosevelt**. In 1903 he declared Pelican Island in Florida a refuge for the **brown pelican**, protecting a **species** that was close to **extinction**. In 1906 Congress closed all refuges to **hunting**, and in 1908, it established the National **Bison** Range refuge in Montana to protect that **endangered species**.

The refuge system continued to expand later in the century, with a primary emphasis on migratory waterfowl. In 1929 Congress passed the Migratory Bird Convention Act, followed by the Migratory Bird Hunting Stamp Act of 1934, which provided funding for waterfowl reserves. **Wetlands** now make up roughly 75 percent of the national wildlife refuges and serve as linked management units along the major waterfowl flyways.

The second focus in the expansion of the refuge system has been the need to protect endangered and **rare species**. Several acts have been passed for this purpose, going as far back as the Migratory Bird Treaty Act of 1918, but most recently the **Endangered Species Act** of 1973. For example, the **whooping crane** is protected by a series of national wildlife refuges in Texas, Oklahoma, and Kansas which are linked to **wildlife management** areas in Kansas and Nebraska, and these are linked to a national wildlife area in Saskatchewan and their primary breeding grounds in a Canadian **national park**.

A third recent focus has been on the addition of high-latitude **wilderness** in Alaska. In 1980 Congress passed the Alaska National Interest Conservation Lands Act which added roughly 54 million acres (22 million ha) of Alaskan land to the national **wildlife refuge** system.

The refuge system now consists of slightly over 400 refuges, which encompass 99 million acres (40 million ha) of land in parcels ranging from 2.5 acres (1 ha) to 17 million acres (7 million ha) in size. It is administered by the U.S. **Fish and Wildlife Service**, which was consolidated under the **U.S. Department of the Interior** in 1940. As it is officially written, the mandate is to provide, preserve, restore, and manage a national network of land and water for the benefit of society. The wording of the mandate has resulted in an open policy approach, and NWRs have been used for a variety of activities, some of which seem to many incompatible with the ideal of a refuge. For example, a consequence of having financial support from the sale of duck stamps has been the opening of refuges to waterfowl hunting. Other activities, such as **fertilizer runoff** and other **agricultural pollution** have seriously impacted the **ecological integrity** of several reserves in the western United States, including **Kesterson National Wildlife Refuge** in California's San Joaquin Valley.

Perhaps the most significant test of the government's ability to maintain the ecological integrity of the refuge system came over the fight to open the **Arctic National Wildlife Refuge** for oil exploration. This is the second largest reserve in the system, and perhaps the most spectacular in terms of wilderness values. Although the proposal had the support of two successive Presidents, Congress rejected it. Critics argued that it was inconsistent to maintain that oil production would benefit the country when it was earmarked for export. And the disaster caused by the *Exxon Valdez* **made oil companies' claims of environmental sensitivity seem to lack credibility.**

The general challenges now facing the refuge system arise both from pressure to develop in order to accommodate increased visitor demand and the vague criteria defined in the National Wildlife Refuge Administration Act of 1966 for multiple use. *See also* Forest Service; Migration; National Park Service; Oil drilling; Pinchot, Gifford; Wilderness Study Area; Wildlife management

Native landscaping

Landscaping with native plants (also called indigenous plants) can help improve the **environment** in several ways. North America is home to thousands of indigenous plants that over many thousands of years have evolved and adapted to specific North American habitats such as prairies, deciduous forests, deserts, or coastal plains. However, many plants that are common today were brought to North America from different biogeographic areas by European and Asian immigrants. Some of the most common landscaping plants used in North America today, such as zinnias (*Zinnia elegans*) or Kentucky bluegrass (*Poa pratensis*), are not native to areas where they now thrive.

Plants brought from their native **habitat** to another **ecosystem** are called non-native or alien plants. For example, early colonists brought with them seeds from their homes in Europe to plant for food or use for landscaping. Likewise, some native North American plants, such as **tobacco** *Nicotiana* sp.), were taken back to Europe. Many of these plants thrived in their new homes.

While new plants were being imported, increased colonization altered the character of the land in North America. Forests were felled and prairies plowed under to convert large swatches of land to farming. Some of the newly introduced plants grew better under these altered conditions than did native North American plants. Some **species** of non-native plants begin to take over the habitat of native plants, forcing the native plants out. Sometimes this was intentional, as when a non-native plant was grown for food or planted for landscaping. Other times, it was accidental, as when a non-native plant used in landscaping escaped the garden and began to grow uncontrolled in the wild.

One way to maintain native plants is to set aside large **nature** preserves and protected parks where native plants can grow undisturbed. Native landscaping hopes to protect our plant heritage in another way, by planting native species in home gardens and landscaped areas such as the grounds around corporate headquarters, on college campuses, and in city parks. Native landscaping in many cases saves water, reduces **pesticide** use, and maintains unique systems of indigenous plants and animals.

Landscaping around urban and suburban homes usually employs only several dozen kinds of plants, from turf grass to evergreens for foundation plantings to decorative flowers. This typical landscape supports little variety in insect and animal life. Lawns and evergreen hedges offer little protective cover for small mammals, and streams or ponds that provide water and a home for animals are often diverted or drained to make way for development. Gardeners may plant beds of decorative annual flowers, but these are usually not adequate for feeding bees, butterflies, and other insects that depend on nectar.

Native plants, on the other hand, have evolved in complex communities. Often the land can support a greater variety of native plant species. In some cases these plant communities naturally enrich the **soil** to make it fertile enough to support still more species. These communities shelter a variety of animals and insects that in turn help plant species thrive by pollinating the plants and distributing their seeds. The plants and animals are tied together in ecosystems where all have evolved to live with specific natural conditions (for example, high soil acidity, low rainfall, or high mineral content of the soil).

The number of different species of plants and animals that form an ecological community determines the **biodiversity** of that community. Many urban and suburban landscapes have low biodiversity, because they support only a few different species. Even landscaped lawns and gardens that support a high level of biodiversity are considered of low value by ecologists when the plants are almost entirely alien.

Native landscaping helps to develop biocommunities that improve the **ecological integrity** of the land. The biodiversity of the area returns more closely to its original state. This is considered a desirable goal by ecologists. Often when native plants are grown in their natural habitat, they require fewer resources (water, **fertilizer**) than alien species because they have evolved to suit the natural conditions of the area. For example, the turf grass that covers most American yards evolved in the cool, rainy summers of Northern Europe. Consequently, in many parts of the United States there is inadequate natural rainfall in the summer for this grass to thrive and, people must water their lawns to keep the non-native grass green and healthy. Alien flowers and non-native ornamental trees may also be more susceptible to disease and pests. Native landscaping is a valuable way to cut back on the use of chemical pesticides and fertilizers, as well as water, because native plants in the proper site can support themselves without this supplemental care.

In some cases, plants introduced from other places have become pests, growing abundantly and choking off native growth. These plants are called invasive plants, because they invade or take over the habitat of native plants. One example is **purple loosestrife** (*Lythrum salicaria*), an ornamental plant brought from Europe in the 1800s. It has grown so well in some areas of North America that it is now a significant threat to the biodiversity of wetland habitats. Alien insects that arrive on introduced plants can also threaten native plants with **extinction**. Native landscapers help root out invasive plants and restore the original plant communities.

The trend toward landscaping with native plants emerged in the United States in the 1980s and 1990s. Some communities (for example in the San Francisco Bay area) now have local native plant societies that hold annual sales of native plants to help the gardener interested in native landscaping. The first step towards native landscaping is usually to reduce the amount of lawn. Some gardeners have replaced traditional turf lawn with a meadow or **prairie** planting of native grasses. Some environments, such as **desert**, do not naturally support any kind of grass. Native landscapers in these regions tend to favor drought-tolerant perennials. In dry areas, landscaping with native plants can be an important element in landscaping for **water conservation** (called xeriscaping).

Another move toward native landscaping is to border a turf lawn with plantings of native perennials, shrubs, and trees. Many native plants are quite ornamental, but the native

landscaper may also select plants based on kind of ecological community they support. Native planting might include shrubs that bear fruits eaten by local birds and mammals, early spring wildflowers that provide nectar for insects just emerging from winter dormancy, or nut trees to feed squirrels through the winter. A native landscape might also include flowers that will attract local butterflies. The resulting landscape may prove to easier and cheaper to maintain than a traditional planting, need few or no pesticides or fertilizers, use less water, and provide food and habitat for a diverse animal population.

Natural gas

Naturally occurring gas that primarily contains **methane**, CH_4. A fossil fuel like **coal** and **petroleum**, it is the hottest and cleanest burning of these fuels and is increasingly touted as a substitute for petroleum. It is, however, an explosion hazard in coal mines and an unwanted byproduct of **anaerobic digestion** in landfills. It is most commonly found with petroleum or at depths which vaporize oil. Use is hampered by **transportation** difficulties and risks, and thus it is limited to pipelines and compression tanks. Huge quantities exist as unconventional sources, including **coal gasification** and conversion to **methanol**. *See also* Liquified natural gas

Natural resources

Natural resources, unlike man-made resources, exist independently of human labor. Natural resources can be viewed as an endowment or a gift to humankind. These resources are, however, not unlimited and must be used with care. Some natural resources are called "fund resources" because they can be exhausted through use, like the burning of **fossil fuels**. Other fund resources such as metals can be dissipated or wasted if they are discarded instead of being reused or recycled. Some natural resources can be used up like fund resources, but they can renew themselves if they're not completely destroyed. Examples of the latter would include the **soil**, forests, and fisheries.

Because of **population growth** and a rising standard of living, the demand for natural resources is steadily increasing. For example, the rising demand for minerals, if continued, will deplete the known and expected reserves within the coming decades.

The world's industrialized nations are consuming **nonrenewable resources** at an accelerating pace, with the United States ranking first on a per capita basis. With only 5% of the global population, Americans consumes 30% of the world's resources. Because of their tremendous demand for goods, Americans have also created more waste than is generated by any other country. The **environment** in the United States has been degraded with an ever-increasing volume and variety of contaminants. In particular, a complex of synthetic **chemicals** with a vast potential for harmful effects on human health has been created. The long-term effects of a low dosage of many of these chemicals in our environment will not be known for decades. The three most important causes for global environmental problems today are population growth, excessive resource consumption, and high levels of **pollution**. All of these threaten the natural resource base.

Natural Resources Defense Council

Founded in 1970, the Natural Resources Defense Council (NRDC) is a major national environmental organization active in most areas of concern to environmentalists and conservationists. It boasts a membership of 500,000 nationwide and had an annual budget in 2001 of nearly $41 million dollars. These resources are employed in the organization's quest to use science and law to create "a world in which human beings live in harmony with our environment." NRDC seeks a sustainable society and believes that economic growth can continue only if it does not destroy the natural resources that fuel it. NRDC's stated goals include access to pure air and water and safe food for every human being. NRDC's philosophy is based increasingly on a belief in the inherent sanctity of the natural **environment**. As its mission statement proclaims, NRDC ultimately "strives to help create a new way of life for humankind, one that can be sustained indefinitely without fouling or depleting the resources that support all life on Earth." The organization is headquartered in New York City, with regional offices in Washington, D.C., San Francisco, and Los Angeles.

Generally regarded as an influential and highly effective mainstream environmental organization, NRDC's successes have often come from its expertise in lobbying governmental officials, helping to draft environmental laws, and working with public utility officials to reduce wasteful and environmentally destructive practices. NRDC has also made considerable use of the judicial system in defense of environmental causes and retains on its staff some of the nation's top environmental lawyers.

Among its many notable achievements, NRDC has been instrumental in setting national standards for building and appliance efficiency. It collaborated with over a dozen states and Canadian provinces on the reform of **electric utilities** and helped the Soviet Union design an electrical planning program in the late 1980s. NRDC has helped protect dozens of national forests from abusive **logging** practices, including forests in the Greater Yellowstone **ecosystem** and old-growth forests in the Sierra Nevada. In addition, NRDC led the fight for the national phase-out of **lead** from **gasoline** and lobbied intensively for passage of the 1990 **Clean Air Act**. It was a sponsor of the Nuclear Non-Proliferation Act and helped prove that an underground **nuclear test ban** treaty could be verified.

The NRDC is active in several areas, including Air and Energy; Global Warming; Clean Water and Oceans; Wildlife and Fish; Parks, Forests, and Wildlands; Toxic **Chemicals** and Health; **Nuclear Weapons** and Waste; Cities and Green Living; and Environmental Legislation. Its ongoing projects are numerous and include the continuing protection of the **Arctic National Wildlife Refuge** and California coastal areas from **oil drilling**. NRDC continues to monitor the policies and practices of the **Environmental Protection Agency** (EPA) and has convinced the EPA to strengthen its rules regarding the reporting of releases of toxic substances into the environment. It has lobbied the government to designate new funds for the protection of **endangered species**; to include environmental standards and controls in the **North American Free Trade Agreement**; to close loopholes in proposed rules for controlling **acid rain**; and to strengthen **automobile pollution** standards, as well as on many other environmental issues. In addition, the organization publishes a quarterly magazine of environmental thought and opinion, entitled *OnEarth* (formerly the *Amicus Journal*).

Internationally, NRDC seeks the eventual elimination of nuclear weapons, the protection of **habitat** and ecosystems in developing countries, and the worldwide phaseout of **chlorofluorocarbons**. It promotes alternative agricultural techniques to reduce the use of pesticides, the strengthening of regulations governing the disposal of waste in landfills, and the testing and treatment of poor children for lead **poisoning**. NRDC is urging states and municipalities to stop the **ocean dumping** of sewage **sludge** and encouraging **mass transit** programs as an alternative to automobiles and new highways.

The NRDC urged President Bill Clinton to create six new National Monuments and protect 4 million new acres from development in the United States. By 2002, the NRDC had initiated a "BioGems Defender" program, which relies upon the e-mails of 250,000 members to pressure lawmakers to protect endangered areas or **species**. With the help of actor Robert Redford, who e-mailed letters on behalf of the BioGems program, the NRDC helped protect the Arctic **National Wildlife Refuge** (ANWR) from oil drilling in 2002. The NRDC also made headlines in 2002 when it successfully sued the George W. Bush Administration, under the Freedom of Information Act, to release documents produced by the National **Energy Policy** Development Group concerning U.S. energy policies.

Natural selection

see **Evolution**

Nature

The word nature stems from the Latin *natura*, whose meaning ranges from "birth" to "the order of things." In English, nature comprises all plants, animals, and ecosystems, as well as the biological and nonbiological materials and processes of our planet. This range of meaning narrows if we consider the use of the word *natural*. Something is natural if it is not artificial, if it pertains to or comes from the natural world. When we speak of bears, mountains, or **evolution** and say, "they are natural," we mean they are neither human nor created by humans. Thus the concept of nature is often restricted to beings, things, or processes which are not human in origin.

Conceptual and empirical inquiries into nature loosely center on eight questions. The first question is a scientific one, which simply asks what constitutes nature: What are its essential properties and how shall we classify them? The second seeks purpose in nature, asking whether the earth is a designed home for humankind or an accident of cosmic history. A third question explores the effect of the natural **environment** on human physiology, psychology and culture, examining whether nature determines who we are or constrains what we can do. A fourth examines the metaphors used to understand nature: Is nature an organism subject to death or a machine of fungible parts? The fifth question studies how nature changes: Is it dynamic, changing as a result of internal processes, or static, changing in response to external human disturbances? A sixth surveys how people have transformed the natural world, and the seventh queries whether human beings and their societies are part of or separate from nature. The final question investigates whether nature has a structure of intrinsic moral values: Does nature have values or a good of its own, and if so, should human beings respect these values or promote this good?

We lack unambiguous answers to these questions, though the questions are important in themselves, for they help us clarify our assumptions about nature. Humans, for example, have emerged from the evolutionary processes of nature. Thus our thoughts and actions are certainly natural, yet our societies and technologies are unique in the natural world, and the scope of our impact on nature is without precedent in other **species**. It seems that while we are part of nature biologically, we are separate from the rest of nature in our social and technological characteristics, and to declare humanity natural or non-natural is unhelpful. The best alternative may be to accept the ambiguity of our relationship to nature, conceiving of humankind as relatively natural and non-natural depending on the time, place, and activity. *See also* Bioregionalism; Deep ecology; Ecosophy; Environmental attitudes/values; Environmental ethics; Environmentalism; Humanism; Speciesism

Nature Conservancy, The

The Nature Conservancy is America's fourth-largest environmental organization, with 1 million members and a budget of over $300 million. It owns or helps manage over 1,400 nature preserves worldwide, covering more than 12 million acres (4.8 million ha) (2 million acres [809,000 ha] of which is owned outright by the organization) in the United States alone. It is the largest private system of nature sanctuaries in the world, helping like-minded partner organizations to preserve more than 80 million acres (3.2 million ha) (7 million acres [2.8 million ha] of which The Nature Conservancy manages directly) in the Asia Pacific, Canada, the Caribbean and Latin America.

The organization is dedicated to protecting nature and its animal inhabitants by preserving their habitats. This is accomplished with a strategic, science-based planning process, called Conservation by Design. Conservation by Design helps The Nature Conservancy identify the highest-priority places (landscapes and seascapes) that, if conserved, promise to ensure **biodiversity** (the variety of life that can be found on Earth—plants, animals, **fungi**, and micro-organisms—as well as to the communities that they form and the habitats in which they live) over the long term. Conservation is achieved by the organization through: buying and managing ecologically important areas; negotiating agreements to manage areas without holding title to them, partnerships or **conservation easements**; offering training to partner organizations and government agencies that manage land; educating people who live in ecologically sensitive areas about the importance of biodiversity and helping them to live in better harmony with the natural **environment**; working with resource-based industries to alter their business practices to

have less environmental impact; and helping government agencies work together and better allocate public resources toward conservation.

The organization was incorporated in 1951 by American Richard Pough, who had been inspired by the British government's nature preserves of the same name. Unlike the English version, Pough's organization was funded privately. The Conservancy's early years were difficult financially, but Pough eventually secured two major endowments that made the society solvent: a $100,000 donation from Mrs. DeWitt Wallace, co-owner of *Readers Digest*, and a $55-million bequest from Minnesota Mining heiress Katharine Ordway. Most of the latter money went for land purchases. Subsequent purchases have acquired millions of acres, although some tracts are later traded or sold to the government, individuals, or other environmental organizations.

One example of The Nature Conservancy's international programs is the *Debt for Nature Swaps* that have been contracted in Central America. These allow The Nature Conservancy, in conjunction with the Department of Defense, to conduct ecological inventories and supervise over 25 million acres (10 million ha). Other projects, such as Parks in Peril, have given The Conservancy charge of over 28 million acres (11.3 million ha) in Latin America and the Caribbean. In the United States, a partnership with **Ducks Unlimited** restored riparian forests and **wetlands** in several states. A three-year program called The Rivers of the Rockies, spent $5 million to preserve 20 sites along Colorado rivers and tributaries. Similar projects are underway in other states as well.

The Nature Conservancy cooperates with federal land and **wildlife** agencies, as well as other environmental associations, and is instrumental in helping to identify land of critical environmental interest. In addition to its local and foreign activities in land preservation, the Nature Conservancy identifies and protects animal life, especially the "rarest of the rare," those **species** most in need of preservation.

In November, 2001, the Nature Conservancy and the United States **Forest Service** signed a Memorandum of Understanding (MOU) to promote cooperation and partnership as the two organizations work to preserve, protect, and monitor forests and grassland ecosystems. The MOU is in effect for five years, during which The Nature Conservancy and the Forest Service will work together to, among other things, protect migratory bird **habitat**, prevent the spread of invasive species, and to carry out prescribed burns in natural areas to promote biodiversity and **ecosystem health**. The two organizations will also jointly establish outreach, educational, and training programs for communities, and will promote partnerships and liaisons with foreign and local governments, tribal interests, landowners, and non-government agencies.

In response to its mission statement, which is "to preserve the plants, animals and natural communities that represent the diversity of life on Earth by protecting the lands and waters they need to survive." The Nature Conservancy instigated its "$1 Billion Campaign," which commits the organization to the investment of one billion dollars to save 200 of "the world's last great places,". As of the middle of 2002, more than $960 million had been raised toward this goal. The organization maintains its Heritage database at its headquarters in Arlington, Virginia, in which **endangered species** are ranked by status both globally and within each state.

Dr. Scott Nearing (1883 – 1983)

American conservationist

A prolific and iconoclastic writer, a socialist, and a conservationist, Scott Nearing—along with his wife Helen—is now considered the "great-grandparent" of the back-to-the-land movement. Nearing was born August 6, 1883, in Morris Run, Pennsylvania. He is the author of nearly fifty books and thousands of pamphlets and articles, some of which have become classics of modern **environmentalism**.

Originally a law student at the University of Pennsylvania, Nearing received his B.S. from that university in 1905 and a Ph.D. in economics in 1909. He was the secretary of the Pennsylvania Child Labor Commission from 1905 to 1907. He taught economics at the Wharton School, at Swarthmore College, and at the University of Toledo in Toledo, Ohio. In 1915, he was dismissed from his position at the Wharton School for his politics, particularly his position on child labor. A pacifist, he was arrested during World War I and charged with obstructing recruitment for the armed forces. He was a Socialist candidate for United States Congress in 1919. His socialism, his pacifism, and his politics in general made it increasingly difficult for him to find and maintain teaching positions after 1917, and he supported himself for the rest of his life by writing, lecturing, and farming.

In 1932, Nearing and his wife bought a small, dilapidated farm in Vermont, hoping, in their words, "to live

sanely and simply in a troubled world." They restored the land and removed or rebuilt the buildings there. They farmed organically and without machinery, feeding themselves from their garden, and making and selling maple sugar. They wrote about their experiences in *The Maple Sugar Book* (1950) and *Living the Good Life* (1954). Their small farm became a mecca for people seeking both to simplify their lives and to live in harmony with **nature**, as well as each other.

In his 1972 autobiography, *The Making of a Radical,* Nearing wrote that the attempt "to live simply and inexpensively in an affluent society dedicated to extravagance and waste" was the most difficult project he had ever undertaken, but also the most physically and spiritually rewarding. He defined the good life he was striving towards as life stripped to its essentials—a life devoted to labor and learning, to doing no harm to humans or animals, and to respecting the land. As he wrote in his autobiography, he tried to live by three basic principles: "To learn the truth, to teach the truth, and to help build the truth into the life of the community."

Confronted by the growth of the recreational industry in Vermont during the 1950s, particularly the construction of a ski resort near them, the Nearings sold their property and moved their farm to Harborside, Maine, where Scott Nearing died on August 24, 1983, just over two weeks after his one-hundredth birthday.

Reviled as a radical for most of his life, Nearing's critique of the wastefulness of modern consumer society, his emphasis on smallness, self-reliance, and the restoration of ravaged land, as well as his **vegetarianism**, have struck a responsive chord in many Americans since the late 1960s. He is considered by some as the representative of twentieth century American counterculture, and he has inspired activists throughout the environmental movement, from the editors of *The Whole Earth Catalog* and the founders of the first **Earth Day** to proponents of appropriate technology. He was made an honorary professor emeritus of economics at the Wharton School in 1973.

Nekton

Nekton are aquatic animals that swim or move freely in the water. Their movement is generally not controlled by waves and currents. Nekton include fish, squid, marine mammals, and marine reptiles. They live in the sea, lakes, rivers, ponds, and other bodies of water.

Fish are a major segment of the nektonic animals, with approximately 14,500 kinds of fish living in the ocean. Many nekton live near the ocean surface because food is abundant there. Other nekton live in the deep ocean.

Most nekton are chordates, animals with bones or cartilage. This category of nekton includes **whales**, **sharks**, bony fish, turtles, snakes, eels, **dolphins**, porpoises, and **seals**.

Molluscan nekton like squid and octopus are invertebrates, animals with no bones. Squid, octopus, clams, and oysters are mollusks. However, molluscan nekton have no outer shells.

Molluscan nekton like squid and octopus are invertebrates, animals with no bones. Squid, octopus, clams, and oysters are mollusks. However, molluscan nekton have no outer shells.

Arthopod nekton are invertebrates like shrimp. Many arthropod live on the ocean floor.

Most nektonic mammals live only in water. However, walruses, seals, and sea otters can exist on land for a time. Other nekton mammals include **manatees** and dugongs, whale-like animals that live in the Indian Ocean.

Nematicide

see **Pesticide**

Neoplasm

Neoplasm results in the formation of both benign and, more particularly, malignant tumors or cancers. A neoplasm is a mass of new cells, which proliferate without control and serve no useful function. This lack of control is particularly marked in malignant tumors (**cancer**). The difference between a benign tumor and a malignant one is that the former remains at its site of origin while the latter acquires the ability to escape from its original location, migrate to another place, and invade and colonize other tissues and organs. This results in the death of the surrounding cells as the neoplasm grows rapidly.

Neotropical migrants

Birds that migrate each year between the American tropics and higher latitudes, especially in North America, are known as neotropical migrants. So called because they migrate from the tropics of the "new world" (the Western hemisphere), neotropical migrants are a topic of concern because many **species** have been declining in recent years, and because they are vulnerable to **habitat** destruction and other hazards in both winter and summer ranges. One survey of 62 forest-dwelling migrant bird species found that 44 declined significantly from 1978–1987. Migrants' dependence on nesting and feeding habitat in multiple regions, usually in different countries, makes **conservation** difficult, since habitat protection often requires cooperation between multiple countries. In addition, it is often unclear whose fault it is when populations fall. Most of the outcry over neotropical migrants has been raised in the United States and Canada, where summer bird populations have thinned noticeably in recent decades. Conservationists in northern latitudes tend to attribute bird disappearances to the destruction of tropical forests and other winter habitat. In response, governments in Mexico, Central America, and South America argue that loss of suitable summer nesting habitat, as well as summer feeding and shelter requirements, are responsible for the decline of migratory birds.

About 250 species of birds breed in North America and winter in the south. In the southern and western United States 50-60% of breeding birds are migrants, a number that rises to 80% in southern Canada and to 90% in the Canadian sub-arctic. Among the familiar migrants are species of orioles, hummingbirds, sandpipers and other wading birds, herons and bitterns, flycatchers, swallows, and almost all warblers. Half of these winter in Mexico, the Bahamas, and the Greater Antilles islands. Some 30 species winter as far south as the western **Amazon Basin** and the foothills of the Andes Mountains, where forest clearance poses a significant threat. Species most vulnerable to habitat loss may be those that require large areas of continuous habitat, especially the small woodland birds, and aquatic birds whose wetland habitats are being drained, filled, or contaminated in both summer and winter ranges.

In addition to habitat loss, neotropical migrants suffer from agricultural pesticides, which poison both food sources and the birds themselves. The use of pesticides, including such persistent **chemicals** as **dichlorodiphenyl-trichloroethane** (DDT), has risen in Latin America during the same period that **logging** has decimated forest habitat. Furthermore, some ecologists argue that migrants are especially vulnerable in their winter habitat because winter ranges tend to be geographically more restricted than summer ranges. Sometimes an entire population winters in just a few islands, swamps, or bays. Any habitat damage, **pesticide** use, or predation could impact a large part of the population if the birds concentrate in a small area.

Population declines are by no means limited to loss of wintering grounds. An estimated 40% of North America's eastern deciduous forests, the primary breeding grounds of many migrants, have either been cleared or fragmented. **Habitat fragmentation** is the term used to describe breaking up a patch of habitat into small, dispersed units, or dissecting a patch of habitat with roads or suburban developments. This problem is especially severe on the outskirts of urban areas, where suburbs continue to cut into the surrounding countryside. For reasons not fully understood, neotropical migrants appear to be more susceptible to habitat fragmentation than short-distance migrants or species that remain in residence year round. Hazards of fragmentation include nesting failure due to predation (often by raccoons, snakes, crows, or jays), nesting failure due to **competition** with human-adapted species such as starlings and English sparrows, and **mortality** due to domestic house cats. (An Australian study of house cat predation estimated that 500,000 cats in the state of Victoria had killed 13 million small birds and mammals, including 67 different native bird species.) In addition to hazards in their summer and winter ranges, threats along **migration** routes can impact migratory bird populations. Loss of stop-over **wetlands**, forests, and **grasslands** can reduce food sources and protective cover along migration routes. Sometimes birds are even forced to find alternative migration paths.

European-African migrants suffer similar fates and risks to those of American migrants. In addition to wetland **drainage**, habitat fragmentation, and increased pesticide use, Europeans and Africans also continue to hunt their migratory birds, a hazard that probably impacts American migrants but that is little documented here. It is estimated that in Italy alone, some 50 million songbirds are killed each year as epicurean delicacies. **Hunting** is also practiced in Spain and France, as well as in African countries where people truly may be short of food.

One of the principal sources of data on bird population changes is the North American Breeding Bird Survey, an annual survey conducted by volunteers who traverse a total of 3,000 established transects each year and report the number of breeding birds observed. While this record is by no means complete, it provides the best available approximation of general trends. Not all birds are disappearing. Some have even increased slightly, as a consequence of reduced exposure to DDT, a pesticide outlawed in the United States because it poisons birds, and because of habitat restoration efforts. However the BBS has documented significant and troubling declines in dozens of species.

Declines in migrant bird populations alarm many people because birds are often seen as indicators of more general **ecosystem health**. Birds are highly visible and their disappearance is noticeable, but they may indicate the simultaneous declines of insects, amphibians, fish, and other less visible groups using the same habitat areas.

Neritic zone

The portion of the marine **ecosystem** that overlies the world's continental shelves. This subdivision of the **pelagic zone** includes some of the ocean's most productive water. This productivity supports a food chain culminating in an abundance of commercially important fish and shellfish and is largely a consequence of abundant sunlight and nutrients. In the shallow water of the neritic zone, the entire water column may receive sufficient sunlight for **photosynthesis**. Nutrients are delivered to the area by terrestrial **runoff** and through resuspension from the bottom by waves and currents. Runoff and dumping of waste also deliver pollutants to the neritic zone, and this area is consequently among the ocean's most polluted.

Neurotoxin

Neurotoxins are a special class of metabolic poisons that attack nerve cells. Disruption of the nervous system as a result of exposure to neurotoxins is usually quick and destructive. Neurotoxins are categorized according to the nature of their impact on the nervous system. Anesthetics (ether, chloroform, halothane), **chlorinated hydrocarbons** (DDT, Dieldrin, Aldrin), and **heavy metals** (**lead**, **mercury**) disrupt the **ion** transport across cell membranes essential for nerve action. Common pesticides, including carbamates such as Sevin, Zeneb and Maneb and the organophosphates such as Malathion and Parathion, inhibit acetylcholinesterase, an **enzyme** that regulates nerve signal transmission between nerve cells and the organs and tissues they innervate.

Environmental exposure to neurotoxins can occur through a variety of mechanisms. These include improper use, improper storage or disposal, occupational use, and accidental spills during distribution or application. Since the identification and ramifications of all neurotoxins are not fully known, there is risk of exposure associated with this lack of knowledge.

Cell damage associated with the introduction of neurotoxins occurs through direct contact with the chemical or a loss of oxygen to the cell. This results in damage to cellular components, especially in those required for the synthesis of protein and other cell components.

The symptoms associated with **pesticide poisoning** include eye and skin irritation, miosis, blurred vision, headache, anorexia, nausea, vomiting, increased sweating, increased salivation, diarrhea, abdominal pain, slight bradycardia, ataxia, muscle weakness and twitching, and generalized weakness of respiratory muscles. Symptoms associated with poisoning of the central nervous system include giddiness, anxiety, insomnia, drowsiness, difficulty concentrating, poor recall, confusion, slurred speech, convulsions, coma with the absence of reflexes, depression of respiratory and circulatory centers, and fall in blood pressure.

The link between environmental neurotoxin exposure and neuromuscular and brain dysfunction has recently been identified. Physiological symptoms of Alzheimer's disease, amyotrophic lateral sclerosis (ALS, or Lou Gehrig's disease), and lathyrism have been identified in populations exposed to substances containing known neurotoxins. For example studies have shown that heroin addicts who used synthetic heroin contaminated with methylphenyltetrahydropyridine developed a condition which manifests symptoms identical to those associated with Parkinson disease. On the island of Guam, the natives who incorporate the seeds of the false sago plant (*Cycas circinalis*) into their diet develop a condition very similar to ALS. The development of this condition has been associated with the specific nonprotein amino **acid**, B methylamino-1-alanine, present in the seeds.

Neutron

A subatomic particle with a mass of a proton and no electric charge. It is found in the nuclei of all atoms except hydrogen-1. A free neutron is unstable and decays to form a proton and an electron with a half life of 22 minutes. Because they have no electric charge, neutrons easily penetrate matter, including human tissue. They constitute, therefore, a serious health hazard. When a neutron strikes certain nuclei, such as that of uranium-235, it fissions those nuclei, producing additional neutrons in the process. The **chain reaction** thus initiated is the basis for **nuclear weapons** and **nuclear power**. *See also* Nuclear fission; Radioactivity

Nevada Test Site

The Nevada Test Site (NTS) is one of two locations (the South Pacific being the other) at which the United States has conducted the majority of its **nuclear weapons** tests. The site was chosen for weapons testing in December 1950 by President Harry S. Truman and originally named the Nevada Proving Ground. The first test of a nuclear weapon was carried out at the site in January 1951 when a B-50 bomber dropped a bomb for the first of five tests in "Operation Ranger."

The Nevada Test Site is located 65 miles (105 km) northwest of Las Vegas. It occupies 1,350 square miles (3,497 km^2), an area slightly larger than the state of Rhode Island. Nellis Air Force Base and the Tonopath Test Range surround the site on three sides.

Over 3,500 people are employed by NTS, 1,500 of whom work on the site itself. The site's annual budget is about $450 million, a large percentage goes for weapons testing and a small percentage which is spent on the **radioactive waste** storage facility at nearby **Yucca Mountain**.

The first nuclear tests at the site were conducted over an area known as Frenchman Flat. Between 1951 and 1962, a total of fourteen atmospheric tests were carried out in this area to determine the effect of nuclear explosions on structures and military targets. Ten underground tests were also conducted at Frenchman Flat between 1965 and 1971.

Since 1971, most underground tests at the site have been conducted in the area known as Yucca Flat. These tests are usually carried out in **wells** 10 ft (3 m) in diameter and 600 ft (182 m) to one mile (1.6 km) in depth. On an average, about twelve tests per year are carried out at NTS.

Some individuals have long been concerned about possible environmental effects of the testing carried out a NTS. During the period of atmospheric testing, those effects (**radioactive fallout**, for example) were relatively easy to observe. But the environmental consequences of underground testing have been more difficult to determine.

One such consequence is the production of earthquakes, an event observed in 1968 when a test code-named "Faultless" produced a fault with a vertical displacement of 15 ft (5 m). Such events are rare, however, and of less concern than the release of radioactive materials into **groundwater** and the escape of radioactive gases through venting from the test well.

In 1989, the Office of Technology Assessment (OTA) of the United States Congress carried out a study of the possible environmental effects from underground testing. OTA concluded that the risks to humans from underground testing at NTS are very low indeed. It found that, in the first place, there is essentially no possibility that any release of radioactive material could go undetected. OTA also calculated that the total mount of radiation a person would have received by standing at the NTS boundary for every underground test conducted at the site so far would be about equal to 1/1000 of a single chest x-ray or equivalent to 32 minutes more of exposure to natural **background radiation** in a person's lifetime. *See also* Groundwater pollution; Hazardous waste; Nuclear fission; Radiation exposure; Radioactive decay; Radioactivity

New Madrid, Missouri

Those who think that earthquakes are strictly a California phenomenon might be amazed to learn that the most powerful **earthquake** in recorded American history occurred in the middle of the country near New Madrid (pronounced MAD-rid), Missouri. Between December 16, 1811, and February 7, 1812, about 2,000 tremors shook southeastern

Missouri and adjacent parts of Arkansas, Illinois, and Tennessee. The largest of these earthquakes is thought to have had a magnitude of 8.8 on the Richter scale, making it one of the most massive ever recorded.

Witnesses reported shocks so violent that trees 6 feet (2 meters) thick were snapped like matchsticks. More than 150,00 acres (60,000 ha) of forest were flattened. Fissures several yards wide and many miles long split the earth. Geysers of dry sand or muddy water spouted into the air. A trough 150 miles (242 km) long, 40 miles (64 km) wide, and up to 30 feet (9 m) deep formed along the fault line. The town of New Madrid sank about 12 feet (4 m). The Mississippi River reversed its course and flowed north rather than south past New Madrid for several hours. Many people feared that it was the end of the world.

One of the most bizarre effects of the tremors was **soil** liquefaction. Soil with high water content was converted instantly to liquid mud. Buildings tipped over, hills slid into the valleys, and animals sank as if caught in quicksand. Land surrounding a hamlet called Little **Prairie** suddenly became a soupy swamp. Residents had to wade for miles through hip-deep mud to reach solid ground. The swamp was not drained for nearly a century.

Some villages were flattened by the earthquake, while others were flooded when the river filled in subsided areas. The tremors rang bells in Washington, D.C., and shook residents out of bed in Cincinnati, Ohio. Since the country was sparsely populated in 1812, however, few people were killed.

The situation is much different now, of course. The damage from an earthquake of that magnitude would be calamitous. Much of Memphis, Tennessee, only about 100 miles (160 km) from New Madrid, is built on **landfill** similar to that in the Mission District of San Francisco where so much damage occurred in the earthquake of 1990. St. Louis had only 2,000 residents in 1812; nearly a half million live there now. Scores of smaller cities and towns lie along the fault line and transcontinental highways and pipelines cross the area. Few residents have been aware of earthquake dangers or how to protect themselves. Midwestern buildings generally are not designed to survive tremors.

Anxiety about earthquakes in the Midwest was aroused in 1990 when climatologist Iben Browning predicted a 50-50 chance of an earthquake 7.0 or higher on or around December 3, in or near New Madrid. Browning based his prediction on calculations of planetary motion and gravitational forces. Many geologists were quick to dismiss these techniques, pointing out that seismic and geochemical analyses predict earthquakes much more accurately than the methods he used. Although there were no large earth quakes along the New Madrid fault in 1990, the **probability** of a major tremor there remains high.

While the general time and place of some earthquakes have been predicted with remarkable success, mystery and uncertainty still abound concerning when and where "the next big one" will occur. Will it be in California? Will it be in the Midwest? Or will it be somewhere entirely unexpected? Meanwhile, residents of New Madrid are planning emergency exit routes and stocking up on camping gear and survival supplies.

New Source Performance Standard

The Clean Air Acts of 1963 and 1967 gave to the **Environmental Protection Agency** (EPA) the authority to establish **emission standards** for new and modified stationary sources. These standards are called new source performance standards (NSPS) and are determined by the best **emission** control technology available, the energy needed to use the technology, and its overall cost. An example of an NSPS is the standard set for plants that make Portland cement. Such plants are allowed to release no more than 0.30 pounds of emissions for each ton of raw materials used and to produce an emission with no more than 20 percent opacity.

New York Bight

A bight is a coastal embayment usually formed by a curved shoreline. The New York Bight forms part of the Middle Atlantic Bight, which runs along the east coast of the United States. The dimensions of the New York Bight are roughly square, encompassing an area that extends out from the New York-New Jersey shore to the eastern limit of Long Island and down to the southern tip of New Jersey. The apex of the bight, as it is known, is the northwestern corner, which includes the **Hudson River** estuary, the Passaic and Hackensack River estuaries, Newark Bay, Arthur Kill, Upper Bay, Lower Bay, and Raritan Bay.

The New York Bight contains a valuable and diverse **ecosystem**. The waters of the bight vary from relatively fresh near the shore to **brackish** and salty as one moves eastward, and the range of **salinity**, along with the islands and shore areas present within the area, have created a diver-

sity of environmental conditions and habitats, which include marshes, woods, and beaches, as well as highly developed urban areas. The portion of the bight near the shore lies directly in the path of one of the major transcontinental migratory pathways for birds, the North Atlantic **flyway**.

The New York Bight has a history of extremely intensive use by humans, especially at the apex, and here environmental impacts have been most severe. Beginning with the settlement of New York City in the 1600s, the bight area has supported one of the world's busiest harbors and largest cities. It receives more than two billion gallons per day of domestic sewage and industrial **wastewater**. Millions of gallons of **nonpoint source runoff** also pours into the bight during storms, and regulated **ocean dumping** of dredge spoils also occurs.

Numerous studies have shown that the sediments of the bight, particularly at the apex, have been contaminated. Levels of **heavy metals** such as **lead**, **cadmium** and **copper** in the sediments of the apex are of special concern because they far exceed current guidelines on acceptable concentrations. Similarly, organic pollutants such as **polychlorinated biphenyls** (PCBs) from transformer oil and **polycyclic aromatic hydrocarbons** (PAHs) degraded from **petroleum** compounds are also in the sediments at levels high enough to be of concern. Additionally, the sewage brings enormous quantities of **nitrogen** and **phosphorus** into the bight which promotes excessive growth of algae.

The continual polluting of the bight since the early days of settlement has progressively reduced its capacity as a food source for the surrounding communities. The oyster and shellfishing industry that thrived in the early 1800s began declining in the 1870s, and government advisories currently prohibit shellfishing in the waters of the bight due to the high concentrations of contaminants that have accumulated in shellfish. Fishing is highly regulated throughout the area, and health advisories have been issued for consumption of fish caught in the bight. The bottom-dwelling worms and insect larvae in the sediments of the apex consist almost entirely of **species** that are extremely tolerant of **pollution**; sensitive species are absent and **biodiversity** is low.

There are, however, some reasons to be optimistic. The areas within the bight closest to the open ocean are much cleaner than the highly degraded apex. In these less-impacted areas, the bottom-dwelling communities have higher species diversity and include species that prefer unimpacted conditions. Since the 1970s, enforcement of the **Clean Water Act** has helped greatly in reducing the quantities of untreated wastewater entering the bight. Some fish species that had been almost eliminated from the area have returned, and today striped bass again swim up the Hudson River to spawn. *See also* Algal bloom; Environmental stress; Marine pollution; Pollution control; Sewage treatment; Storm runoff

Niche

The term niche is used in **ecology** with a variety of distinct meanings. It may refer to a spatial unit or to a function unit. One definition focuses on niche as a role claimed exclusively by a **species** through **competition**. The word is also used to refer to "utilization distribution" or the frequency with which populations use resources. Still, niche is well enough established in ecology that Stephen Jay Gould can label it as "the fundamental concept" in the discipline, "an expression of the location and function of a species in a habitat." Niche is used to address such questions as what determines the species diversity of a **biological community**, how similar organisms coexist in an area, how species divide up the resources of an **environment**, and how species within a community affect each other over time.

Niche has not been applied very satisfactorily in the ecological study of humans. Anthropologists have used it perhaps most successfully in the study of how small pre-industrial tribal groups adapt to local conditions. Sociologists have not been very successful with niche, subdividing the human species by occupations or roles, creating false analogies that do not come very close to the way niche is used in biology. More recently, sociologists have extended niche to help explain organizational behavior, though again distorting it as an ecological concept.

Some attempts were made to build on the vernacular sense of niche as in "he found his niche," a measure of how individual human beings attain multidimensional "fit" with their surroundings. But this usage was again criticized as too much of a distortion of the original meaning of niche in biology. The word and related concepts remain common, however, and are widely understood in vernacular usage to

describe how individual human beings make their way in the world.

The niche concept has not been much employed by environmental scientists, though it might be helpful in attempts to understand the relationships between humans and their environments, for instance. Efforts to formulate niche or a synonym of some sort for use in the study of such relationships will probably continue. The best use of niche might be in its utility as an indicator of the richness and diversity of **habitat**, serving in this way as an indicator of the general health of the environment.

Nickel

Nickel is a heavy metal, and it can be an important toxic chemical in the **environment**. Natural **pollution** by nickel is associated with soils that have a significant presence of a mineral known as serpentine. Serpentine-laced soils are toxic to nonadapted plants, and although the most significant toxic stressor is a large concentration of nickel, sometimes the presence of cobalt and/or chromium, along with high **pH** and an impoverished supply of nutrients also create a toxic environment. Serpentine sites often have a specialized **flora** dominated by nickel-tolerant **species**, many of which are endemic to such sites. Nickel pollution can occur through human influence as well—most often in the vicinity of nickel smelters or refineries. The best-known example of a nickel-polluted environment occurs around the town of **Sudbury, Ontario**, where smelting has been practiced for a century. *See also* Heavy metals and heavy metal poisoning

Nitrates and nitrites

Nitrates and nitrites are families of chemical compounds containing atoms of **nitrogen** and oxygen. Occurring naturally, nitrates and nitrites are critical to the continuation of life on the earth, since they are one of the main sources from which plants obtain the element nitrogen. This element is required for the production of amino acids which, in turn, are used in the manufacture of proteins in both plants and animals.

One of the great transformations of agriculture over the past century has been the expanded use of synthetic chemical fertilizers. Ammonium nitrate is one of the most important of these fertilizers. In recent years, this compound has ranked in the top fifteen among synthetic **chemicals** produced in the United States.

The increased use of nitrates as **fertilizer** has led to some serious environmental problems. All nitrates are soluble, so whatever amount is not taken up by plants in a field is washed away into **groundwater** and, eventually, into rivers, streams, ponds, and lakes. In these bodies of water, the nitrates become sources of food for algae and other plant life, resulting in the formation of algal blooms. Such blooms are usually the first step in the eutrophication of a pond or lake. As a result of eutrophication, a pond or lake slowly evolves into a marsh or swamp, then into a bog, and finally into a meadow.

Nitrates and nitrites present a second, quite different kind of environmental issue. These compounds have long been used in the preservation of red meats. They are attractive to industry not only because they protect meat from spoiling, but also because they give meat the bright red color that consumers expect.

The use of nitrates and nitrites in meats has been the subject of controversy, however, for at least twenty years. Some critics argue that the compounds are not really effective as preservatives. They claim that preservation is really effected by the table salt that is usually used along with nitrates and nitrites. Furthermore, some scientists believe that nitrates and nitrites may themselves be carcinogens or may be converted in the body to a class of compounds known as the nitrosamines, compounds that are known to be carcinogens.

In the 1970s, the **Food and Drug Administration** (FDA) responded to these concerns by dramatically cutting back on the quantity of nitrates and nitrites that could be added to foods. By 1981, however, a thorough study of the issue by the **National Academy of Sciences** showed that nitrates and nitrites are only a minor source of nitrosamine compared to smoking, drinking water, cosmetics, and industrial chemicals. Based on this study, the FDA finally decided in January 1983 that nitrates and nitrites are safe to use in foods. *See also* Agricultural revolution; Cancer; Cigarette smoke; Denitrification; Drinking-water supply; Fertilizer runoff; Nitrification; Nitrogen cycle; Nitrogen waste

Nitrification

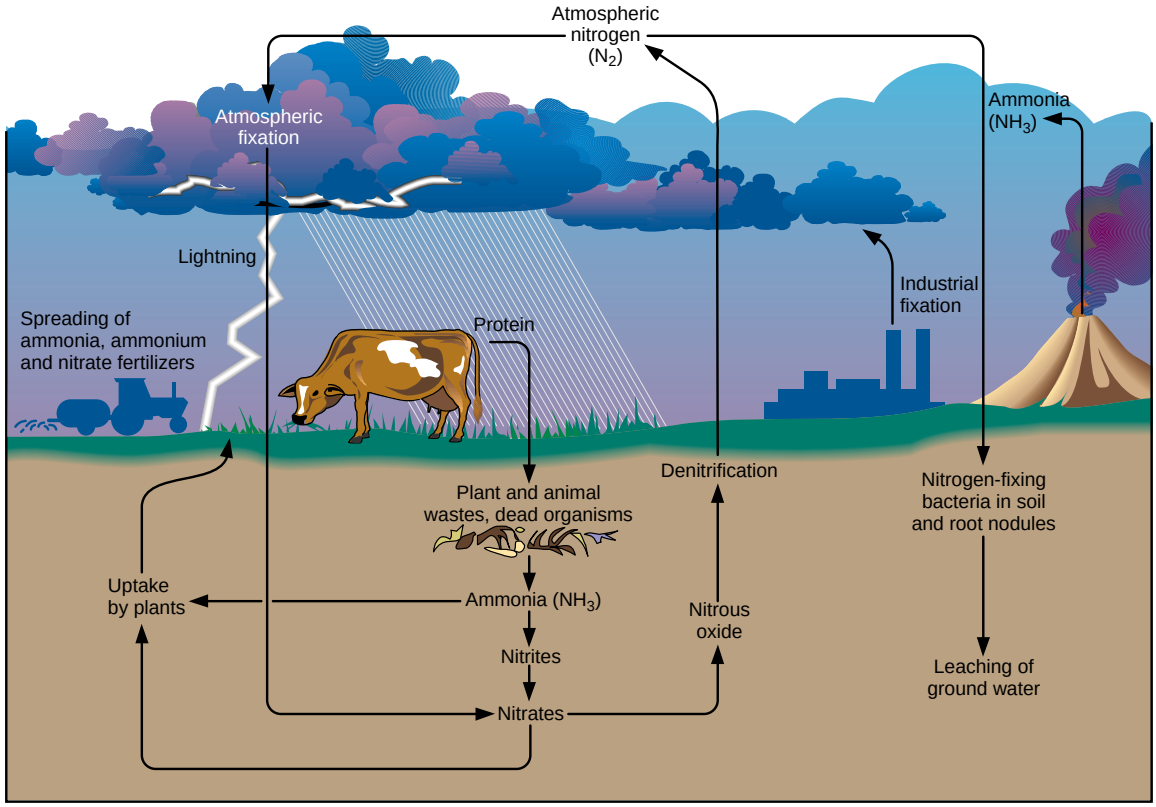
A biological process involving the conversion of nitrogen-containing organic compounds into **nitrates and nitrites**. It is accomplished by two groups of chemo-synthetic bacteria that utilize the energy produced. The first step involves the oxidation of ammonia to nitrite, and is accomplished by *Nitrosomas* in the **soil** and *Nitrosoccus* in the marine **environment**. The second step involves the oxidation of **nitrites** into **nitrates**, releasing 18 kcal of energy. It is accomplished by *Nitrobacter* in the soil and *Nitrococcus* in salt water. Nitrification is an integral part of the **nitrogen cycle**, and is usually considered a beneficial process, since it converts organic **nitrogen** compounds into nitrates which can be absorbed by green plants. The reverse process of nitrification, occurring in oxygen-deprived environments, is called **denitrification** and is accomplished by other **species** of bacteria.

Nitrites

see **Nitrates and nitrites**

Nitrogen

Comprising about 78% of the earth's **atmosphere**, nitrogen (N_2) has an atomic number of seven and an atomic weight of 14. It has a much lower solubility in water than in air—there is approximately 200 times more nitrogen in the atmosphere than in the ocean. The main source of gaseous nitrogen is volcanic eruptions; the major nitrogen sinks are synthesis of nitrate in electrical storms and biological **nitrogen fixation**. All organisms need nitrogen. It forms part of the chlorophyll molecule in plants, it forms the nitrogen base in DNA and RNA, and it is an essential part of all amino acids, the building blocks of proteins. Nitrogen is needed in large amounts for **respiration**, growth, and reproduction. **Nitrogen oxides** (NO_x), produced mainly by motor vehicles and internal **combustion** engines, are one of the main contributors to **acid rain**. They react with water molecules in the atmosphere to form nitric **acid**. *See also* Nitrates and nitrites; Nitrogen cycle



Nitrogen cycle

Nitrogen is a macronutrient essential to all living organisms. It is an integral component of amino acids which are the building blocks of proteins; it forms part of the nitrogenous bases common to DNA and RNA; it helps make up ATP, and it is a major component of the chlorophyll molecule in plants. In essence, life as we know it cannot exist without nitrogen.

Although nitrogen is readily abundant as a gas (it comprises 79 percent of atmospheric gases by volume), most organisms cannot use it in this state. It must be converted to a chemically usable form such as ammonia (NH_3) or nitrate (NO_3) for most plants, and amino acids for all animals. The processes involved in the conversion of nitrogen to its various forms comprise the nitrogen cycle. Of all the **nutrient** cycles, this is considered the most complex and least well understood scientifically. The processes that make up the nitrogen cycle include **nitrogen fixation**, ammonification, **nitrification**, and **denitrification**.

Nitrogen fixation refers to the conversion of atmospheric nitrogen gas (N_2) to ammonia (NH_3) or nitrate (NO_3). The latter is formed when lightning or sometimes cosmic radiation causes oxygen and nitrogen to react in the **atmosphere**. Farmers are usually delighted when electrical storms move through their areas because it supplies "free" nitrogen to their crops, thus saving money on **fertilizer**. Ammonia is produced from N_2 by a special group of **microbes** in a process called biological fixation, which accounts for about 90 percent of all fixed N_2 each year worldwide. This process is accomplished by a relatively small number of **species** of bacteria and blue-green algae, or blue-green

The nitrogen cycle. (Illustration by Hans & Cassidy.)

bacteria. The most well known of these nitrogen-fixing organisms are the bacteria in the genus *Rhizobium* which are associated with the root nodules of legumes. The legumes attract these bacteria by secreting a chemical into the **soil** that stimulates the bacteria to multiply and enter the root hair tips. The resultant swellings contain millions of bacteria and are called root nodules, and here, near the soil's surface, they actively convert atmospheric N_2 to NH_3, which is taken up by the plant. This is an example of a symbiotic relationship, where both organisms benefit. The bacteria benefit from the physical location in which to grow, and they also utilize sugars supplied by the plant photosynthate to reduce the N_2 to NH_3. The legumes, in turn, benefit from the NH_3 produced. The energetic cost for this nutrient is quite high, however, and legumes typically take their nitrogen directly from the soil rather than from their bacteria when the soil is fertilized.

Although nitrogen fixation by legume bacteria is the major source of biological fixation, other species of bacteria are also involved in this process. Some are associated with non-legume plants such as toyon (*Ceanothus*), silverberry (*Elaeagnus*), water fern (*Azolla*), and alder (*Alnus*). With the exception of the water fern, these plants are typically pioneer species growing in low-nitrogen soil. Other nitrogen-fixing bacteria live as free-living species in the soil. These include microbes in the genera *Azotobacter* and *Clostridium*, which live in **aerobic** and **anaerobic** sediments, respectively.

Blue-green algae are the other major group of living organisms which fix atmospheric N_2. They include approximately forty species in such genera as *Aphanizomenon*, *Anabaena*, *Calothrix*, *Gloeotrichia*, and *Nostoc*. They inhabit both soil and freshwater and can tolerate adverse and even extreme conditions. For example, some species grow in hot springs where the water is 212°F (100°C), whereas other species inhabit glaciers where the temperature is 32°F (0°C). The characteristic bluish-green coloration is a telltale sign of their presence. Some blue-green algae are found as pioneer species invading barren soil devoid of nutrients, particularly nitrogen, either as solitary individuals or associated with other organisms such as **lichens**. Flooded rice fields are another prime location for nitrogen-fixing blue-green algae.

Perhaps the most common environments where blue-green algae are found are lakes and ponds, particularly when

the body of water is eutrophic—containing high concentrations of nutrients, especially **phosphorus**. Algae can reach bloom proportions during the warm summer months and are often considered a nuisance because they float on the surface, forming dense scum. The resultant odor following **decomposition** is usually pungent, and fish such as catfish often acquire an off-flavor taste from ingesting these algae.

The next major component of the nitrogen cycle is ammonification. It involves the breakdown of organic matter (in this case amino acids) by decomposer organisms to NH_3, yielding energy. It is therefore the reverse reaction of amino **acid** synthesis. Dead plant and animal tissues and waste materials are broken down to amino acids and eventually NH_3 by the saprophagous bacteria and **fungi** in both soil and water.

Nitrification is a biological process where NH_3 is oxidized in two steps, first to NO_3 and next to nitrate (NO2). It is accomplished by two genera of bacteria, *Nitrosomonas* and *Nitrobacter* in the soil, and *Nitrosococcus* and *Nitrococcus* in salt water. Since nitrification is an oxidation reaction, it requires oxygenated environments.

Dentrification is the reverse reaction of nitrification and occurs under anaerobic conditions. It involves the breakdown of **nitrates and nitrites** into gaseous N_2 by **microorganisms** and fungi. Bacteria in the genus *Pseudomonas* (e.g., *P. dentrificans*) reduce NO_3 in the soil.

The cycling of nitrogen in an **ecosystem** is obviously complex. In aquatic ecosystems, nitrogen can enter the food chain through various sources, primarily surface **runoff** into lakes or rivers, mixing of nutrient-rich bottom waters (normally only during spring and fall turnovers in north temperate lakes), and biological fixation of atmospheric nitrogen by blue-green algae. **Phytoplankton** (microscopic algae) then rapidly take up the available nitrogen in the form of NH_3 or NO_3 and assimilate it into their tissues, primarily as amino acids. Some nitrogen is released by leakage through cell membranes. Herbivorous **zooplankton** that ingest these algae convert their amino acids into different amino acids and excrete the rest. Carnivorous or omnivorous zooplankton and fish that eat the herbivores do the same. Excretion (usually as NH_3 and urea) is thus a valuable nutrient **recycling** mechanism in aquatic ecosystems. Different species of phytoplankton actively compete for these nutrients when they are limited. Decomposing bacteria in the lake, particularly in the top layer of the bottom sediments, play an important role in the breakdown of dead organic matter which sinks to the bottom. The cycle is thus complete.

The cycling of nitrogen in marine ecosystems is similar to that in lakes, except that nitrogen lost to the sediments in the deep open water areas is essentially lost. Recycling only occurs in the nearshore regions, usually through a process called upwelling. Another difference is that marine phytoplankton prefer to take up nitrogen in the form of NH_3 rather than NO_3.

In terrestrial ecosystems, NH_3 and NO_3 in the soil is taken up by plants and assimilated into amino acids. As in aquatic habitats, the nitrogen is passed through the **food chain/web** from plants to herbivores to carnivores, which manufacture new amino acids. Upon death, **decomposers** begin the breakdown process, converting the organic nitrogen to inorganic NH_3. Bacteria are the main decomposers of animal matter and fungi are the main group that break down plants. Shelf and bracket fungi, for example, grow rapidly on fallen trees in forests. The action of termites, bark beetles, and other insects that inhabit these trees greatly speed up the process of decomposition.

There are three major differences between nitrogen cycling in aquatic versus terrestrial ecosystems. First, the nitrogen reserves are usually much greater in terrestrial habitats because nutrients contained in the soil remain accessible, whereas nitrogen released in water and not taken up by phytoplankton sinks to the bottom where it can be lost or held for a long time. Secondly, nutrient recycling by herbivores is normally a more significant process in aquatic ecosystems. Thirdly, terrestrial plants prefer to take up nitrogen as NO_3 and aquatic plants prefer NH_3.

Forces in **nature** normally operate in a balance, and gains are offset by losses. So it is with the nitrogen cycle in freshwater and terrestrial ecosystems. Losses of nitrogen by detritrification, runoff, **sedimentation**, and other releases equal gains by fixation and other sources.

Humans, however, have an influence on the nitrogen cycle that can greatly change normal pathways. Fertilizers used in excess on residential lawns and agricultural fields add tremendous amounts of nitrogen (typically as urea or ammonium nitrate) to the target area. Some of the nitrogen is taken up by the vegetation, but most washes away as surface runoff, entering streams, ponds, lakes, and the ocean. This contributes to the accelerated eutrophication of these bodies of water. For example, periodic unexplained blooms of toxic dinoflagellates off the coast of southern Norway have been blamed on excess nutrients, particularly nitrogen, added to the ocean by the fertilizer runoff from agricultural fields in southern Sweden and northern Denmark. These algae have caused massive dieoffs of **salmon** in the **mariculture** pens popular along the coast, resulting in millions of dollars of damage. Similar circumstances have contributed to blooms of other species of dinoflagellates, creating what are known as red tides. When filter-feeding shellfish ingest these algae, they become toxic, both to other fishes and humans. Paralytic shellfish **poisoning** may result within thirty minutes, leading to impairment of normal nerve conduction, difficulty in breathing, and possible death. Saxo-

toxin, the toxin produced by the dinoflagellate *Gonyaulax*, is fifty times more lethal than strychnine and curare.

Other forms of human intrusion into the nitrogen cycle include harvesting crops, **logging**, sewage, animal wastes, and exhaust from automobiles and factories. Harvesting crops and logging remove nitrogen from the system. The other processes are point sources of excess nitrogen. Autos and factories produce nitrous oxides (NO_x) such as nitrogen dioxide (NO_2), a major air pollutant. NO_2 contributes to the formation of **smog**, often irritating eyes and leading to breathing difficulty. It also reacts with water vapor in the atmosphere to form weak nitric acid (HNO_3), one of the major components of **acid rain**. *See also* Agricultural pollution; Air pollution; Aquatic weed control; Marine pollution; Nitrogen waste; Soil fertility; Urban runoff

Nitrogen fixation

Nitrogen fixation is the biological process by which atmospheric nitrogen gas (N_2) is converted into ammonia (NH_3). Nitrogen is an essential **nutrient** for the growth of all organisms, as it is a component of proteins, nucleic acids, amino acids, and other cellular constituents. Nearly 79% of the earth's **atmosphere** is N_2, but N_2 is unavailable for use by most organisms, because it is nearly inert due to the triple bonds between the two nitrogen atoms. To utilize nitrogen, organisms require that it be fixed (combined) in the form of ammonium (NH_4) or nitrate ions (NO_3).

The bacteria that accomplish nitrogen fixation are either free-living or form symbiotic associations with plants or other organisms such as termites or protozoa. The free-living bacteria include both **aerobic** and **anaerobic** bacteria, including some **species** that are photosynthetic.

The most well-known nitrogen-fixing symbiotic relationships are those of legumes (e.g., peas, beans, clover, soybeans, and alfalfa) and the bacteria *Rhizobium*, which is present in nodules on the roots of the legumes. The plants provide the bacteria with carbohydrates for energy and a stable **environment** for growth, while the bacteria provide the plants with usable nitrogen and other essential nutrients. The bacteria invade the plant and cause formation of the nodule by inducing growth of the plant host cells. The *Rhizobium* are separated from the plant cells by being enclosed in a membrane. The cultivation of legumes as green manure crops to add nitrogen by incorporation into the **soil** is a long-established agricultural process.

Frankia, a type of bacteria belonging to the bacterial group actinomycetes, form nitrogen-fixing root nodules with several woody plants, including alder and sea buckhorn. These trees are pioneer species that invade nutrient-poor soils.

The photosynthetic nitrogen-fixing bacteria cyanobacteria (also known as blue-green algae) live as free-living organisms or as symbionts with **lichens** in pioneer habitats such as **desert** soils. They also form a symbiotic association with the fern *Azolla*, which is also found in lakes, swamps, and streams. In rice paddies, *Azolla* has been grown as a green manure crop; it is plowed into the soil to release nitrogen before planting of the rice crop.

The nitrogen fixed by the nitrogen-fixing bacteria is utilized by other living organisms. After their death, the nitrogen is released into the environment through **decomposition** processes and continues to move through the **nitrogen cycle**.

Nitrogen oxides

Five oxides of **nitrogen** are known: N_2O, NO, N_2O_3, NO_2, and N_2O_5. Environmental scientists usually refer to only two of these, nitric oxide and nitrogen dioxide, when they use the term nitrogen oxides. The term may also be used, however, for any other combination of the five compounds. Nitric oxide and nitrogen dioxide are produced during the **combustion** of **fossil fuels** in automobiles, jet aircraft, industrial processes, and electrical power production. The gases have a number of deleterious effects on human health, including irritation of the eyes, skin, respiratory tract, and

lungs; chronic and acute **bronchitis**; and heart and lung damage. *See also* Ozone; Smog

Nitrogen scrubbing

see **Raprenox (nitrogen scrubbing)**

Nitrogen waste

Nitrogen waste is a component of sewage that comes primarily from human excreta and **detergents** but also from fertilizers and such industrial processes as steel-making. Nitrogen waste consists primarily of **nitrates and nitrites** as well as compounds of ammonia. Because they tend to clog waterways and encourage algae growth, nitrogen wastes are undesirable. They present a problem for **wastewater** treatment since they are not removed by either primary or secondary treatment steps. Their removal at the tertiary stage can be achieved only by specialized procedures. Another approach is to use wastewater on farmlands. This use removes about 50 percent of nitrogen wastes from water by turning it into nutrients for the **soil**. *See also* Sewage treatment

Nitrous oxide

Nitrous oxide (N_2O), also called di-nitrogen monoxide, is one of several gaseous oxides of **nitrogen**. It is sometimes referred to as laughing gas, because when inhaled it causes a feeling of intoxication, mild hysteria, and sometimes laughter. The gas is colorless and has a faint odor and slightly sweet taste. It can lessen the sensation of pain and is used as an anesthetic in dentistry and in minor surgery of short duration. For more complex surgery, it is combined with other anesthetics to produce a deeper and longer-lasting state of anesthesia. Nitrous oxide also is commonly used as a propellant for pressurized food products, and sometimes is used in race cars to boost the power of high performance engines. It is one of the few gases capable of supporting **combustion**. In this process, it transfers its oxygen to the material being combusted and is converted to molecular nitrogen (N_2).

Nitrous oxide is an important component of the Earth's upper **atmosphere** at heights above 30 mi (45 km). It is one of the **greenhouse gases**, together with **carbon dioxide**, **methane**, and **ozone**, that allow radiation from the Sun to reach the Earth's surface but prevent the infrared or heat component of sunlight from re-irradiating into space. This leads to the so-called **greenhouse effect**, and results in warmer temperatures at the earth's surface. Greenhouse warming is important in creating surface temperatures suitable for life, but recent studies have shown that the levels of some greenhouse gases are increasing at rates that are a cause for concern. Human-made gases, such as **chlorofluorocarbons**, are also contributing to the greenhouse effect. An increase in the Earth's ability to trap infrared radiation can be expected to result in global **climate** change with wide-ranging consequences.

Concern over greenhouse gases has centered on reports of increasing concentrations of atmospheric **carbon** dioxide (CO_2). Two factors thought to be responsible are the widespread use of **fossil fuels** (which add CO_2 to the atmosphere) and the rapid destruction of tropical rain forests which remove CO_2). The levels of other greenhouse gases may also be changing. Studies indicate that atmospheric levels of nitrous oxide may also be increasing as a result of human activity. Nitrous oxide is produced in **nature** by **microorganisms** acting on nitrogen-containing compounds in the **soil**. Increased use of nitrogen **fertilizer** in lawns, gardens, and agricultural fields may stimulate microbial production of nitrous oxide. Manure and municipal **sludge**, applied as soil enhancers and fertilizers, and burning fossil fuels also may contribute to an increase.

Nitrous oxide production in soils is greatly influenced by soil temperature, moisture level, organic content, soil type, **pH**, and oxygen availability. In agricultural soil, rates of fertilizer application, fertilizer type, tillage practices, crop type, and **irrigation** all influence nitrous oxide production. High soil temperature, moisture, and organic content tend to enhance production, whereas tilling of the soil tends to lower it. The relative importance of each of these factors has not been determined, and further study is needed to develop recommendations to limit harmful nitrous oxide emissions from soils.

Noise pollution

Every year since 1973, the U.S. Department of Housing and Urban Development has conducted a survey to find out what city residents dislike about their **environment**. And every year the same factor has been named most objectionable. It is not crime, **pollution**, or congestion; it is noise--something that affects every one of us every day.

We have known for a long time that prolonged exposure to noises, such as loud music or the roar of machinery, can result in hearing loss. Evidence now suggests that noise-related stress also causes a wide range of psychological and physiological problems ranging from irritability to heart disease. An increasing number of people are affected by noise in their environment. By age forty, nearly everyone in America has suffered hearing deterioration in the higher frequencies. An estimated ten percent of Americans (24 million people) suffer serious hearing loss, and the lives of another 80 million people are significantly disrupted by noise.

What is noise? There are many definitions, some technical and some philosophical. What is music to your ears might be noise to someone else. Simply defined, noise pollution is any unwanted sound or any sound that interferes with hearing, causes stress, or disrupts our lives. Sound is measured either in dynes, watts, or decibels. Note that decibels (db) are logarithmic; that is, a 10 db increase represents a doubling of sound energy.

Noises come from many sources. Traffic is generally the most omnipresent noise in the city. Cars, trucks, and buses create a roar that permeates nearly everywhere. Around airports, jets thunder overhead, stopping conversation, rattling dishes, some times even cracking walls. Jackhammers rattle in the streets; sirens pierce the air; motorcycles, lawnmowers, snowblowers, and chain saws create an infernal din; and music from radios, TVs, and loudspeakers fills the air everywhere.

We detect sound by means of a set of sensory cells in the inner ear. These cells have tiny projections (called microvilli and kinocilia) on their surface. As sound waves pass through the fluid-filled chamber within which these cells are suspended, the microvilli rub against a flexible membrane lying on top of them. Bending of fibers inside the microvilli sets off a mechanico-chemical process that results in a nerve signal being sent through the auditory nerve to the brain where the signal is analyzed and interpreted.

The sensitivity and discrimination of our hearing is remark able. Normally, humans can hear sounds from about 16 cycles per second (hz) to 20,000 hz. A young child whose hearing has not yet been damaged by excess noise can hear the whine of a mosquito's wings at the window when less than one quadrillionth of a watt per cm^2 is reaching the eardrum.

The sensory cell's microvilli are flexible and resilient, but only up to a point. They can bend and then spring back up, but they die if they are smashed down too hard or too often. Prolonged exposure to sounds above about 90 decibels can flatten some of the microvilli permanently and their function will be lost. By age thirty, most Americans have lost 5 db of sensitivity and cannot hear anything above 16,000 Hertz (Hz); by age sixty-five, the sensitivity reduction is 40 db for most people, and all sounds above 8,000 Hz are lost. By contrast, in the Sudan, where the environment is very quiet, even seventy-year-olds have no significant hearing loss.

Extremely loud sounds—above 130 db, the level of a loud rock band or music heard through earphones at a high setting—actually can rip out the sensory microvilli, causing aberrant nerve signals that the brain interprets as a high-pitched whine or whistle. Many people experience ringing ears after exposure to very loud noises. Coffee, aspirin, certain antibiotics, and fever also can cause ringing sensations, but they usually are temporary.

A persistent ringing is called tinnitus. It has been estimated that 94 percent of the people in the United States suffer some degree of tinnitus. For most people, the ringing is noticeable only in a very quiet environment, and we rarely are in a place that is quiet enough to hear it. About 35 out of 1,000 people have tinnitus severely enough to interfere with their lives. Sometimes the ringing becomes so loud that it is unendurable, like shrieking brakes on a subway train. Unfortunately, there is not yet a treatment for this distressing disorder. One of the first charges to the **Environmental Protection Agency** (EPA) when it was founded in 1970 was to study noise pollution and to recommend ways to reduce the noise in our environment. Standards have since been promulgated for noise reduction in automobiles, trucks, buses, motorcycles, mopeds, refrigeration units, power lawnmowers, construction equipment, and airplanes. The EPA is considering ordering that warnings be placed on power tools, radios, chain saws, and other household equipment. The **Occupational Safety and Health Administration** (OSHA) also has set standards for noise in the workplace that have considerably reduced noise-related hearing losses.

Noise is still all around us, however. In many cases, the most dangerous noise is that to which we voluntarily subject ourselves. Perhaps if people understood the dangers of noise and the permanence of hearing loss, we would have a quieter environment.

[*William P. Cunningham Ph.D.*]

Nonattainment area

Any locality found to be in violation of one or more National Ambient Air Quality Standards set by the **Environmental Protection Agency** (EPA) under the provisions of the **Clean Air Act**. However, a nonattainment area for one standard may be an **attainment area** for a different standard. The seven criteria pollutants for which standards were established in 1970 under the Clean Air Act are **carbon monoxide**, **lead**, **nitrogen** dioxide, **ozone** (a key ingredient in **smog**), **particulate** matter, **sulfur dioxide**, and **hydrocarbons**. Violation of National Ambient Air Quality Standards for one of the seven criteria pollutants can have a variety of consequences for an area, including restrictions on permits for new stationary sources of **pollution** (or significant modifications to existing ones), mandatory institution of vehicle emissions inspection programs, or loss of federal funding (including funding unrelated to pollution problems). *See also* Automobile emissions

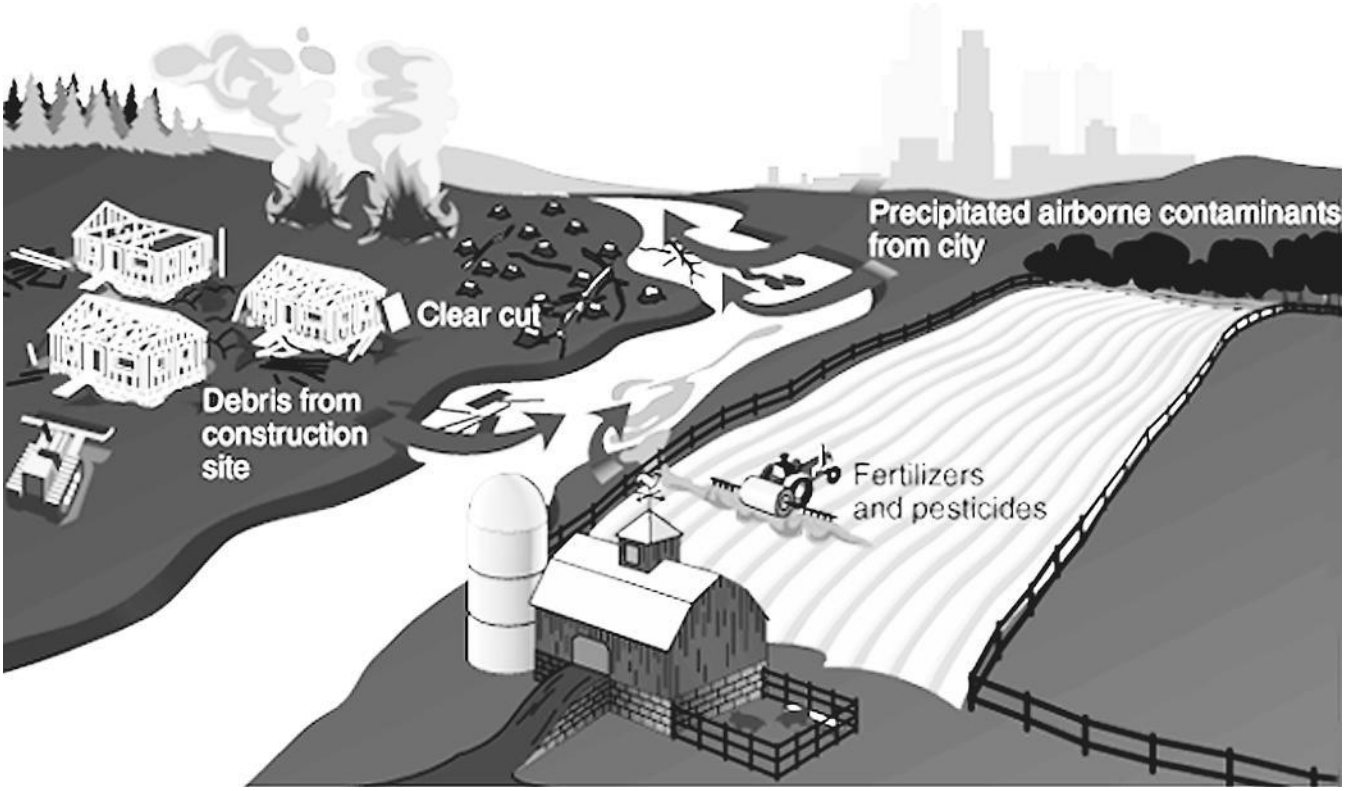
Noncriteria pollutant

Pollutants for which specific standards or criteria have not been established. Although some air pollutants are known to be toxic or hazardous, they are released in relatively small quantities or in locations where individual regulation is not required. Others are not yet regulated because data is insufficient to set definite criteria for acceptable ambient levels or control methods. Political and economic interests have also blocked regulatory action. The **Clean Air Act** Amendments of 1990 required the **Environmental Protection Agency** (EPA) to establish **emission standards** for some 189 toxic air pollutants and 250 source categories, thus changing many noncriteria pollutants to criteria ones. *See also* Criteria pollutant

Nondegradable pollutant

A pollutant that is not broken down by natural processes. Some nondegradable pollutants, like the **heavy metals**, create problems because they are toxic and persistent in the **environment**. Others, like synthetic **plastics**, are a problem because of their sheer volume. One way of dealing with nondegradable pollutants is to reduce the quantity released into the environment either by **recycling** them for **reuse** before they are disposed of, or by curtailing their production. A second method is to find ways of making them degradable. Scientists have been able to develop new types of bacteria, for example, that do not exist in **nature**, but that will degrade plastics. *See also* Decomposition; Pollution

Nongame wildlife



Terrestrial and semi-aquatic vertebrates not normally hunted for sport. The majority of wild vertebrates are contained in this group. In the United States **wildlife** agencies are funded largely by **hunting** license fees and by excise taxes on arms and ammunition used for hunting, and they have had to develop other revenue sources for nongame wildlife. The most common method is the state income-tax checkoff, by which citizens may donate portions of their tax returns to nongame wildlife programs. A limited amount of federal aid for such programs has recently been made available to state wildlife agencies through the Nongame Wildlife Act of 1980. *See also* Game animal

Nongovernmental organization

A nongovernmental organization (NGO) is any group outside of government whose purpose is the protection of the **environment**. The term encompasses a broad range of indigenous groups, private charities, advisory committees, and professional organizations; it includes mainstream environmental groups such as the **Sierra Club** and **Defenders of Wildlife**, and more radical groups such as **Greenpeace** and **Earth First!**

In the United States, NGOs have played a pivotal role in the creation of **environmental policy**, directing lobbying efforts and mobilizing the kind of popular support which have made such changes possible. They have been involved in the protection of many **endangered species** and threatened

Nonpoint sources of water pollution. (Illustration by Hans & Cassidy.)

habitats, including the **northern spotted owl** and the old-growth forests in the Pacific Northwest. Organizations such as **Earthwatch**, **Earth Island Institute**, and **Sea Shepherd Conservation Society** raised international awareness about the environmental dangers of using drift nets in the **commercial fishing** industry. Their campaign included drift-net monitoring, public education, and direct action, and their efforts led to an international ban on this method. NGOs are extensively involved in the current debate about the future of environmental protection and issues such as **sustainable development** and **zero population growth**.

The number of NGOs worldwide is estimated at over 12,000. They have grown rapidly in number and influence during the last 20 years. In 1972, NGOs had little representation at the **United Nations Conference on the Human Environment** in Stockholm, which was called by industrialized nations primarily to discuss **air pollution**. But these groups had become a much more significant international presence by 1992, and over 9,000 NGOs sent delegates to the Earth Summit in Rio de Janeiro, Brazil. The political pressure NGOs were able to bring to bear had an important, if indirect, effect on the long and complicated preparations for the summit. During the summit itself, NGOs organized a "shadow assembly" or **Global Forum** in a park near Guanabara Bay, where they monitored official negotiations and held conferences of their own. *See also* Animal rights; Bioregionalism; Environmental education; Environmental ethics; Environmental monitoring; Environmentalism; Green politics; Greens; United Nations Earth Summit

[*Douglas Smith*]

Nonpoint source

A diffuse, scattered source of **pollution**. Nonpoint sources have no fixed location where they **discharge** pollutants into the air or water as do chimneys, outfall pipes, or other point sources. Nonpoint sources include **runoff** from agricultural fields, **feedlots**, lawns, **golf courses**, construction sites, streets, and parking lots, as well as emissions from quarrying operations, forest fires, and the evaporation of volatile substances from small businesses such as dry cleaners. Unlike pollutants discharged by point sources, nonpoint pollution is difficult to monitor, regulate, and control. Also, it frequently

occurs episodically rather than predictably. Where treatment plants have been installed to control discharge from point sources, nonpoint sources can be responsible for most of the pollution found in bodies of water. As much as 90% of the pollution load in a body of water may come from nonpoint sources. *See also* Water pollution

Nonrenewable resources

Any naturally occurring, finite resources that diminish with use, such as oil and **coal**. In terms of the human timescale, a nonrenewable resource cannot be renewed once it has been consumed. Most nonrenewable resources can only be renewed over geologic time, if at all. All the **fossil fuels** and mineral resources fall into this category. Renewable resources occur naturally and cannot be used up, such as **solar energy** or **wave power**. As resource depletion has become more common, the process of **recycling** has somewhat reduced reliance on virgin nonrenewable resources.

Non-timber forest products

Forest covers 30% of the world's land area. Fifty-six percent of the world's forest is classified as tropical and subtropical and 44% is considered temperate and boreal. Forests are most often valued for their timber resources, however timber is not the only product available from the forest. Forests are also host to an array of non-timber forest products (NTFPs).

NTFPs include berries and fruits, wild mushrooms, honey, gums, spices, nuts, ornamental foliage, mosses and **lichens**, and botanicals used for medicinal, cosmetic, and handicraft purposes. Although there is debate on the matter, some definitions of NTFPs also include fish, wild game, insects, and firewood. NTFPs can also be referred to as; special forest products, non-wood forest products, minor forest products, alternative forest products and secondary forest products. Many NTFPs come from mature, intact forests, illustrating the need to conserve the forests for the vast renewable resources they provide.

People use NTFPs everyday and don't even think about it. Most medicines contain ginseng or other roots that must be harvested in the wild. A very important drug for the treatment of ovarian and other cancers, Taxol, is extracted from the bark of Pacific yew trees. These trees are scarce in number and found predominately in old-growth forests between California and Alaska.

Indigenous people around the world have a long history of using NTFPs in everyday life. They also have a great knowledge and tradition of the medicinal, nutritional, cultural, and spiritual uses of NTFPs. Settler populations moving into areas inhabited by native peoples throughout history have learned of these diverse uses of NTFPs and also developed their own traditions and culture of use.

NTFPs provide market and non-market benefits and commodities for households, communities, and enterprises around the world without the large-scale extraction of timber. In most countries in the world, large-scale industrial **logging** has become the main economic focus in the forest, with timber being at the center of **forest management**. In the last 50 years industrial logging operations have become larger and more mechanized and often controlled by large corporations or central governments. This has left many forest-based communities and forest workers with diminished access to the forest and reduced economic means connected with the forest. Increasing concern for community and **ecosystem health** has brought NTFPs into the spotlight. NTFPs and the development of community-based NTFP enterprises can be seen as important steps towards a diverse, sustainable, multiple-use forest **ecology** and economy.

Although not as large as timber trade values, NTFPs are also a valuable commodity on the global market. According to a 1995 assessment by the Food and Agricultural Organization of the United Nations (FAO), the annual value of international trade in NTFPs for natural honey is $268.2 million, mushrooms and truffles $210.7 million, plants used in pharmacy $689.9 million, nuts $593.1 million, ginseng roots $389.3 million, and spices $175.7 million. The general direction of trade is from developing to developed countries. The **European Union** countries, the United States, and Japan import 60% of the NTFPs traded on the world market. China is the dominant exporter of NTFPs along with India, Indonesia, Malaysia, Thailand and Brazil.

Developed countries import many NTFPs, however, NTFP harvesting and production are also important locally and domestically in the countries of the developed world. For example, researchers estimate that in 1994 the floral and Christmas greens markets alone in Washington, Oregon in the United States and southwest British Columbia, Canada reached a level of US $106.8 million. Mushrooms are also an important product. It is estimated that as many as 36 mushroom **species** are traded commercially in the states of Washington, Oregon and Idaho. In 1992 the wild mushroom market was estimated to be valued at $41.1 million increasing from $21.5 million in 1985.

Because of the nature of the NTFPs and the markets dictating their value, it is difficult to come up with exact figures for the value of different products. The figures above for the value of international trade record only those NTFPs that come onto the world market. Because many people in the world are using NTFPs for their own household

subsistence the figures above only give a partial picture of the total value and use of NTFPs. For instance, the FAO estimates that 80% of the population of the developing world uses NTFPs for health and nutritional needs.

Furthermore, NTFPs have a social and spiritual value for many people making it difficult to assign a dollar value. Economists stumble when trying to assign a value to activities such as, enjoying a couple hours in the forest picking a bucket full of berries to give to a relative or friend. Economists and policy-makers are focusing more attention on these non-market values and attempts are being made to set these values. Quantifying these important non-market values may provide decision makers with tools to better incorporate NTFPs into land-use planning and management.

Knowledge of the economics of NTFPs is limited. And knowledge of the ecology of NTFPs is patchy at best. Of course there are some pockets of extensive knowledge. For example, researchers in Finland forecast the volume of several berry species on a regular basis throughout the harvest season, alerting harvesters and buyers of where the best picking will be, based on weather and on-the-ground reporting.

On the other side of the spectrum, little is known about many of the individual NTFP species and their interaction with other species in the greater forest **ecosystem**. There is a risk that as markets grow for individual NTFPs, they will experience greater harvesting pressures. Lack of scientific knowledge and regulation of harvests may bring over-harvesting in concentrated areas or unexpected uncontrolled market expansion, which could lead to unchecked stress on species with unknown effects on species population and viability. Many NTFP development programs are in fact starting to look to cultivation and agro-forestry alternatives as a way of taking the pressure off of the wild growing species.

As more attention is paid to the opportunities that NTFPs present for multiple-use forestry and locally based economies, it is important that gaps in ecological and economic knowledge be filled. Generally speaking it can be said, that the later years of the twentieth century many regions have witnessed a paradigm shift in forest management from management for timber resources only to **ecosystem management**.

Management of NTFPs presents complex challenges for policy-makers, managers, scientists, enterprises, and communities. There is a need for greater flow of information about the ecology, economy and social issues surrounding NTFP development and management. The list below exemplifies the difficult challenges in developing sustainable management systems for NTFPs. Traditional policy-makers and forest resource managers will be pushed to expand their grasp of the issue and their way of working. NTFP management demands, among other things, **adaptive management** planning, non-linear thinking, and the involvement of multiple stakeholders.

Primary considerations for the sustainable management of NTFPs include

- Understanding the unique biology and ecology of special forest product species
- Anticipating the dynamics of forest communities on a landscape level, delineating present and future areas of high production potential and identifying areas requiring protection
- Developing silvicultural and vegetation management approaches to sustain and enhance production
- Integrating human behavior by monitoring and **modeling** people's responses to management decisions about special forest products
- Conducting necessary inventory, evaluation, and research monitoring

The current non-formal nature of much of the NTFP activity does have its benefits for households and communities. It must be kept in mind when developing NTFP management schemes that regulatory systems must be designed so that they protect NTFP ecology but do not result in reduced access for small enterprises and individual users or user groups. For example, regulatory systems involving difficult bureaucratic processes and fee based permits may make it difficult for small actors with less capital to participate in the commercial and recreational harvest.

In many countries in the developing world, women are the primary actors in NTFP trade. In many countries and cultures women are denied land ownership and decision making power but are able to have access to the forest resources to earn income and provide for the subsistence nutritional and medicinal needs of their families. However, according to the Center for International Forestry Research, in many cases, attempts to formalize the NTFP production and trade have pushed women out of these traditional roles. NTFP development programs designed with women specifically in mind have managed to avoid some of this displacement.

NTFP development offers opportunities for communities and enterprises in the forests of the world. The challenge today is to broaden the view of the forest's economic, ecological and social values to include NTFPs. In adopting this expanded view, policy makers, citizens, scientists, and industry must come together to fill in the gaps of knowledge and to plan the continued and sustainable use of the resources.

Non-Western environmental ethics

Ordinary people are powerfully motivated to do things that can be justified in terms of their religious beliefs. Therefore, distilling **environmental ethics** from the world's living religions is extremely important for global **conservation**. Christianity is a world religion, but so are Islam and Buddhism. Other major religious traditions, such as Hinduism and Confucianism, while more regionally restricted, nevertheless claim millions of devotees. The well-documented effort of Jewish and Christian conservationists to formulate the Judeo-Christian Stewardship Environmental Ethic in biblical terms suggests an important new line of inquiry: How can effective conservation ethics be formulated in terms of other sacred texts? In *Earth's Insights: A Multicultural Survey of Ecological Wisdom*, a comprehensive survey is offered, but to provide even a synopsis of that study would be impossible in this entry. However, a few abstracts of traditional non-Western conservation ethics may be suggestive.

Muslims believe that Islam was founded in the seventh century A.D., by Allah (God) communicating to humanity through the Arabian prophet, Mohammed, who regarded himself to be in the same prophetic tradition as Moses and Jesus. Therefore, since the Hebrew Bible and the New Testament are earlier divine revelations underlying distinctly Muslim belief, the basic Islamic worldview has much in common with the basic Judeo-Christian worldview. In particular, Islam teaches that human beings have a privileged place in **nature**, and, going further in this regard than Judaism and Christianity, that indeed, all other natural beings were created to serve humanity. Hence, there has been a strong tendency among Muslims to take a purely instrumental approach to the human-nature relationship. As to the conservation of **biodiversity**, the Arabian oryx was hunted nearly to **extinction** by oil-rich sheikhs armed with military assault rifles in the cradle of Islam. But callous indifference to the rest of creation in the Islamic world is no longer sanctioned religiously.

Islam does not distinguish between religious and secular law. Hence, new conservation regulations in Islamic states must be grounded in the Koran, Mohammed's book of divine revelations. In the early 1980s, a group of Saudi scholars scoured the Koran for environmentally relevant passages and drafted *The Islamic Principles for the Conservation of the Natural Environment*. While reaffirming "a relationship of utilization, development, and subjugation for man's benefit and the fulfillment of his interests," this landmark document also clearly articulates an Islamic version of stewardship: "he [man] is only a manager of the earth and not a proprietor, a beneficiary not a disposer or ordainer: (Kadr, et al., 1983). The Saudi scholars also emphasize a just distribution of "natural resources," not only among members of the present generation, but among members of **future generations**. And as Norton (1991) has argued, conservation goals are well served when future human beings are accorded a moral status equal to that of those currently living. The Saudi scholars have found passages in the Koran that are vaguely ecological. For example, God "produced therein all kinds of things in due balance" (Kadr, et al., 1983).

Ralph Waldo Emerson and **Henry David Thoreau**, thinkers at the fountainhead of North American conservation philosophy, were influenced by the subtle philosophical doctrines of Hinduism, a major religion in India. Hindu thought also inspired Arne Naess's (1989) contemporary "Deep Ecology" conservation philosophy. Hindus believe that at the core of all phenomena there is only one Reality or Being. God, in other words, is not a supreme Being among other lesser and subordinate beings, as in the Judeo-Christian-Islamic tradition. Rather, all beings are a manifestation of the one essential Being, called *Brahman*. And all plurality, all difference, is illusory or at best only apparent.

Such a view would not seem to be a promising point of departure for the conservation of biological diversity, since the actual existence of diversity, biological or otherwise, seems to be denied. Yet in the Hindu concept of *Brahman*, Naess (1989) finds an analogue to the way ecological relationships unite organisms into a **systemic** whole. However that may be, Hinduism, unambiguously invites human beings to identify with other forms of life, for all life-forms share the same essence. Believing that one's own inner self, *atman*, is identical, as an expression of *Brahman*, with the selves of all other creatures leads to compassion for them. The suffering of one life-form is the suffering of all others; to harm other beings is to harm oneself. As a matter of fact, this way of thinking has inspired and helped motivate one of the most persistent and successful conservation movements in the world, the Chipko movement, which has managed to rescue many of India's Himalayan forests from commercial exploitation (Guha 1989b; Shiva 1989).

Jainism is a religion with a relatively few adherents, but a religion of great influence in India. Jains believe that every living thing is inhabited by an immaterial soul, no less pure and immortal than the human soul. Bad deeds in past lives, however, have crusted these souls over with *karma*-matter. *Ahimsa* (noninjury of all living things) and asceticism (eschewing all forms of physical pleasure) are parallel paths that will eventually free the soul from future rebirth in the material realm. Hence, Jains take great care to avoid harming other forms of life and to resist the fleeting pleasure of material consumption. Extreme practitioners refuse to eat any but leftover food prepared for others, and carefully strain their water to avoid ingesting any waterborne organisms--not for the sake of their own health, but to avoid inadvertently killing other living beings. Less extreme practitioners are strict vegetarians and own few material possessions. The Jains are bidding for global leadership in environmental ethics. Their low-on-the-food-chain and low-level-of-consumption lifestyle is held up as a model of ecological right livelihood (Chappel 1986). And the author of the *Jain Declaration on Nature* claims that the central Jain moral precept of ahimsa "is nothing but environmentalism" (Singhvi, n.d.).

Though now virtually extinct in its native India, Buddhism has flourished for many hundreds of years elsewhere in Asia. Its founder, Siddhartha Gautama, first followed the path of meditation to experience the oneness of Atman-Brahman, and then the path of extreme asceticism in order to free his soul from his body—all to little effect. Then he realized that his frustration, including his spiritual frustration, was the result of desire. Not by obtaining what one desires—which only leads one to desire something more—but by stilling desire itself can one achieve enlightenment and liberation. Further, desire distorts one's perceptions, exaggerating the importance of some things and diminishing the importance of others. When one overcomes desire, one can appreciate each thing for what it is.

When the Buddha realized all this, he was filled with a sense of joy, and he radiated loving-kindness toward the world around him. He shared his enlightenment with others, and formulated a code of moral conduct for his followers. Many Buddhists believe that all living beings are in the same predicament: we are driven by desire to a life of continuous frustration. And all can be liberated if all can attain enlightenment. Thus Buddhists can regard other living beings as companions on the path to Buddhahood and *nirvana*.

Buddhists, no less than Jains and Christians, are assuming a leadership role in the global conservation movement. Perhaps most notably, the Dalai Lama of Tibet is the foremost conservationist among world religious leaders. In 1985, the Buddhist Perception of Nature Project was launched to extract and collate the many environmentally relevant passages from Buddhist scriptures and secondary literature. Thus, the relevance of Buddhism to contemporary conservation concerns could be demonstrated and the level of conservation consciousness and conscience in Buddhist monasteries, schools, colleges, and other institutions could be raised (Davies 1987). Bodhi (1987) provides a succinct summary of Buddhist environmental ethics: "With its philosophic insight into the interconnectedness and thoroughgoing interdependence of all conditioned things, with its thesis that happiness is to be found through the restraint of desire, with its goal of enlightenment through renunciation and contemplation and its ethic on non-injury and boundless loving-kindness for all beings, Buddhism provides all the essential elements for a relationship to the natural world characterized by respect, care, and compassion."

One-fourth of the world's population is Chinese. Fortunately, traditional Chinese thought provides excellent conceptual resources for a conservation ethic. The Chinese word *tao* means way or road. The Taoists believe that there is a *Tao*, a Way, of Nature. That is, natural processes occur not only in an orderly but also in a harmonious fashion. Human beings can discern the *Tao*, the natural well-orchestrated flow of things. And human activities can either be well adapted to the tao, or they can oppose it. In the former case, human goals are accomplished with ease and grace and without disturbing the natural **environment**; but in the latter, they are accomplished, if at all, with difficulty and at the price of considerable disruption of neighboring social and natural systems. Capital-intensive Western technology, such as nuclear **power plants** and industrial agricultural, is very "unTaoist" in esprit and motif.

Modern conservationists find in Taoism an ancient analogue of today's countermovement toward appropriate technology and **sustainable development**. The great Mississippi Valley flood of 1993 is a case in point. The river system was not managed in accordance with the *Tao*. Thus, levees and flood walls only exacerbated the big flood when it finally came. Better to have located cities and towns outside the flood plain and allowed the mighty Mississippi River occasionally to overflow. The rich alluvial soils in the river's floodplains could be farmed in dryer year, but no permanent structures should be located there. That way, the floodwaters could periodically spread over the land, enriching the **soil** and replenishing **wetlands** for **wildlife**, and the human dwellings on higher ground could remain safe and secure. Perhaps the officers of the U.S. **Army Corps of Engineers** should study Taoism. We can hope that their counterparts in China will abandon newfangled Maoism for old-fashioned Taoism before going ahead with their plans to contain, rather than cooperate with, the Yangtze River.

The other ancient Chinese religious worldview is Confucianism. To most people, Asian and Western alike, Confucianism connotes conservativism, adherence to rigid customs

and social forms, filial piety, and resignation to feudal inequality. Hence, it seems to hold little promise as an intellectual soil in which to cultivate a conservation ethic. Ames (1992), however, contradicts the received view: "There is a common ground shared by the teachings of classical Confucianism and Taoism...Both express a 'this-worldly' concern for the concrete details of immediate experience rather than...grand abstractions and ideals. Both acknowledge the uniqueness, importance, and primacy of particular persons and their contributions to the world, while at the same time expressing the ecological interrelatedness and interdependence of this person with his context."

From a Confucian point of view, a person is not a separate immortal soul temporarily residing in a physical body; a person is, rather, the unique center of a network of relationships. Since his or her identity is constituted by these relationships, the destruction of one's social and environmental context is equivalent to self-destruction. Biocide, in other words, is tantamount to suicide.

In the West, since individuals are not ordinarily conceived to be robustly related to and dependent upon their context--not only for their existence but for their very identity--then it is possible to imagine that they can remain themselves and be "better off" at the expense of both their social and natural environments. But from a Confucian point of view, it is expanded from its classic social to its current environmental connotation, Confucianism offers a very firm foundation upon which to build a contemporary Chinese conservation ethic.

No-observable-adverse-effect-level

The NOAEL is the lowest "dose" or exposure level to a non-cancer-causing chemical at which no increase in adverse effects is seen in test animals compared with animals in a control group. First, a NOAEL is determined. For instance, it is established that no adverse effects are seen in test animals after they have been exposed to a set amount, such as an ounce per day for a year, whereas a higher exposure causes adverse effects. Then this level is divided by one or more uncertainty factors to establish an acceptable human exposure level. Regulatory agencies typically use a factor of 10, 100, or 1,000 to account for the uncertainty arising from the fact that the NOAEL is based on an animal study but is being extrapolated to set a "safe" level of exposure for human beings.

North

Often the term "North" refers to the countries located in the northern hemisphere of the globe. Scholars who are concerned with worldwide problems such as global **climate** change, sometimes tend to think of the planet as consisting of two halves, the North and the South. The North, or northern hemisphere, is a region where only about one-fifth of the Earth's population lives, but where four-fifths of its goods and services are consumed. Environmental issues of interest to the North are those related to high technology, high consumption, and high energy use. These are areas are of relatively less concern to those who live in the South. Although the North/South dichotomy may be simplistic, it highlights differences in the way peoples of various nation view global environmental problems.

North American Association for Environmental Education

The North American Association for Environmental Education, founded in 1971, is a nonprofit network for professionals and students working in the field of environmental education. It claims to be the world's largest association of environmental educators, with members in the United States and more than 55 countries. The organization's stated mission is to "go beyond consciousness-raising about these issues. [It] must prepare people to think together about the difficult decisions they have to make concerning environmental stewardship, and to work together to improve and try to solve environmental problems." It advocates a cooperative and nonconfrontational approach to environmental education.

NAAEE conducts an annual conference and produces publications, including a member newsletter, the *Environmental Communicator*, and a *Directory of Environmental Educators*. It also operates a Skills Bank and numerous programs. Several of these programs focus on community-based activities. The VINE (Volunteer-led Investigations of Neighborhood Ecology) Network promotes programs using volunteers to lead children in explorations of the ecology of their urban neighborhoods. The Urban Leadership Collaboratives Program aims to develop collaborative environmental education programs in cities. The Environmental Issues Forums (EIF) Program assists students and adults in working with controversial environmental issues in their communities and nationally.

Other NAAEE programs have a wider focus. The NAAEE Training and Professional Development Institute offers workshops and training events on such topics as fundraising and long-range planning, as well as courses for educators from developing countries in cooperation with United States Assistance for International Development (USAID) and the Smithsonian Institute. The Environmental Education and Training Partnership (EETAP), under a U.S. **Environmental Protection Agency** grant, coordinates a consortium of 18 environmental education organizations that promote training. The NAAEE Policy Institute aims to develop standards for environmental education. Additional NAAEE activities include writing reports to the United States Congress on environmental education issues, reviewing proposals submitted for funding under the National Environmental Education Act of 1990, and testifying to support environmental education legislation and innovative programs. Internationally, the organization has helped to establish environmental education centers in Moscow and Kiev and a program in Thailand, and has assisted with developing educational materials in Sri Lanka.

NAAEE maintains four member sections that represent different contexts of environmental education and conduct individual activities: **Conservation** Education Section, Elementary and Secondary Education Section, Environmental Studies Section, and Nonformal Section (for members working outside of formal school settings).

In 1996, the Conservation Education Association was incorporated into NAAEE.

North American Free Trade Agreement

The North American Free Trade Agreement (NAFTA) is an international trade agreement among the United States, Canada, and Mexico that became effective on January 1, 1994. Pursuant to NAFTA most tariffs among the three countries are being phased out over a period of fifteen years. In addition, the agreement liberalizes rules regulating investment by United States and Canadian firms in Mexico. NAFTA includes side agreements on **environment**, labor, and dealing with import surges. Controversy surrounding the adoption of NAFTA by the United States in 1993 included issues related to trade, employment, immigration, labor law, and environmental protection. And, several years after its effective date, observers continue to debate the wisdom of the agreement. The economic slowdown in the United States that began in 2001 has intensified public debate over NAFTA's provisions.

While NAFTA's adoption was being debated, environmentalists were divided in response to whether or not we are environmentally better off with NAFTA. Thus, its adoption was opposed by some environmental groups and supported by others. Major groups opposing it included the **Sierra Club**, **Greenpeace**, the United States Public Interest Research Group (U.S. PIRG), Citizen's Action, Public Citizen: the Clean Water Fund, and the **Student Environmental Action Coalition**. NAFTA was supported, however, by a coalition of major environmental organizations including the **National Wildlife Federation**, the **World Wildlife Fund**, the **National Audubon Society**, the **Environmental Defense** Council, the **Natural Resources Defense Council**, **Conservation International**, and **Defenders of Wildlife**, and **the Nature Conservancy**. Such division among environmentalists with respect to NAFTA and its consequences for the environment continues through the present day.

NAFTA's provisions

NAFTA is first and overall a trade agreement. Thus, the majority of the provisions within its over 1,200 pages focus on elimination of barriers to trade. Over a period of fifteen years, beginning on January 1, 1994, tariffs on over 9,000 products traded among the United States, Mexico, and Canada are being phased out. In addition, other "non-tariff" barriers to trade are being eased or eliminated.

Elimination of tariffs

Tariffs on approximately 4,500 products traded among the NAFTA parties were eliminated on January 1, 1994, and by 1999 tariffs will remain on only about 3,000 products. The remainder will be phased out by the year 2009. The period during which tariffs are phased out gives producers

time to adjust gradually to competition from products of other NAFTA countries. Those products for which tariffs are being phased out gradually are labeled "sensitive products" and include many farm commodities. For example, to protect Mexican producers, corn and dry beans are being protected through a "phase-out" period for tariffs. Producers in the United States are being protected with respect to sugar, asparagus, orange juice concentrate, and melons.

The **automobile** industry is another area for which NAFTA includes special provisions. NAFTA sets out formulas requiring a certain minimum percentage of content from North America (the three NAFTA parties) for an automobile to qualify for duty-free treatment. By 2002, automobiles must contain 62.5% North American content to qualify for such treatment.

The fact that Mexico agreed to abolish tariffs in certain sectors of the economy is important to U.S. investors. For example, telecommunications in Mexico are underdeveloped, and that country has a poor quality telephone system. By 1998, Mexico phased out all tariffs on telecommunications service and equipment.

Removal of non-tariff barriers to trade

NAFTA removes certain barriers to trade that are not in the form of tariffs. For example, NAFTA allows financial service providers of a NAFTA country to establish banking, insurance, securities operations, and other types of financial services in another NAFTA country. NAFTA also provides U.S. and Canadian firms with greater access to Mexico's energy markets. Under NAFTA, U.S. and Canadian firms can sell products to PEMEX, Mexico's federally owned **petroleum** company. In addition, Mexico has opened operation of self-generation, **cogeneration**, and independent **power plants** in Mexico to investment by U.S. or Canadian firms.

Transportation has also been facilitated by NAFTA. Since 1995, U.S., Mexican, and Canadian firms have been allowed to establish cross-border routes. In the early summer of 2002, the United States signed an agreement allowing Mexican trucks to travel throughout the United States. The long-term effects of transportation agreements are difficult to evaluate, however. **Statistics** for 2001 indicate that truck crossings into the United States from Canada and Mexico fell by 4.2% from their level in 2000. This decrease represents the first annual decline since the agreement among the three countries took effect in 1994. On the other hand, this decrease may be only temporary, as it reflects the impact of tightened border security measures following the terrorist attacks of September 11, 2001.

NAFTA does not create a common market for movement of labor, but it does provide for temporary entry of business people from one NAFTA country into another. The four different categories for such movement of workers include business visitors in marketing, sales and related activities, traders and investors, specified kinds of intracompany transfers, and specified professionals meeting educational or special knowledge requirements.

Dispute resolution

Administration of NAFTA is handled by a Commission of cabinet-level officers each of whom has been appointed by one of the NAFTA countries. The Commission includes a Secretary, who is the chief administrator.

The process for resolution of disputes under NAFTA is cumbersome and time-consuming. When a dispute arises with respect to a NAFTA country's rights under the agreement, a consultation can be requested. If the consultation does not resolve the dispute, the Commission will seek to resolve the dispute through alternative dispute resolution procedures. If those are unsuccessful, the complaining country can request the establishment of a five member arbitration panel which will recommend solutions, monitor results, and, if necessary, impose sanctions.

NAFTA's side agreements

In areas involving labor law and environmental protection, NAFTA's provisions are limited.

Labor side agreement

The North American Agreement on Labor Cooperation, also known as the "Side Agreement on Labor" or "Labor Side Agreement," was negotiated in response to concerns that NAFTA itself did little to protect workers in Mexico, the United States, and Canada. In the Labor Side Agreement, the three countries articulate their desire to improve labor conditions and encourage compliance with labor laws. Each party agrees to enforce its own labor laws, but new laws protecting workers are not established. The Agreement establishes a multiple-step process for dealing with instances in which a NAFTA country has exhibited a "consistent pattern of ... failure to effectively enforce its own occupational safety and health, child labor, or minimum wage labor standards." If the three NAFTA parties cannot agree to a resolution, then a committee of experts can be convened to assist in resolving the dispute.

Seven years after NAFTA was enacted, a number of observers consider its side agreement on labor a conspicuous failure that protected international investors at the expense of ordinary workers in all three countries. In the United States, NAFTA led to the elimination of 800,000 manufacturing jobs. Contrary to predictions in 1995, the agreement did not result in an increased trade surplus with Mexico, but the reverse. As manufacturing jobs disappeared, workers in the United States were downscaled to lower-paying, less-secure services jobs. Employers' threats to move production to Mexico became a powerful weapon for undercutting workers' bargaining power. In Canada, a similar process has

brought about a decline in stable full-time employment as well as damaging Canada's social safety net.

Mexican workers have not benefited from this redistribution of jobs. While some manufacturing jobs did move to Mexico, they are largely confined to *maquiladoras* just across the border. *Maquiladoras* are factories that assemble electronics equipment and small appliances for export. Workers are typically paid low wages and have few rights. The *maquiladoras* are isolated from the rest of the Mexican economy and contribute very little to its development. In addition, the expiration of the duty-free status of *maquiladora* products in 2001 means that these factories are less competitive in the global market. As a result, many foreign companies began to shut down their plants in Mexico in 2002.

Environmental side agreement

The North American Agreement on Environmental Cooperation, also known as the "Environmental Side Agreement," was adopted along with the Labor Side Agreement and was negotiated in response to concerns that the body of NAFTA did little to protect the environment. In the Environmental Side Agreement, the three parties articulate their desire to promote environmental concerns without harming the economy, and promote open public discussion of environmental issues. As in the Labor Side Agreement with respect to labor laws, each party agrees to enforce its own environmental laws, but no new environmental laws are made. The agreement establishes a **Commission for Environmental Cooperation** (CEC) that includes a Secretariat and a Council, which is charged with implementing the side agreement.

The Environmental Side Agreement allows a **nongovernmental organization** (such as an environmental group) or a private citizen to file a complaint with the Commission asserting that a NAFTA country "has shown a persistent pattern of failure to effectively enforce its environmental laws." Thus, such groups and individuals can serve as watchdogs for the Commission.

The Environmental Side Agreement allows a NAFTA country to request a consultation with a second NAFTA country regarding that second country's persistent pattern of failure to enforce its environmental laws. If a resolution is not reached as a result of the consultation, a party can request that the Council meet. If the Council is unable to resolve the dispute, it can convene an arbitration panel, which will study the dispute and issue a report. After the parties submit comments, the report is made final. The parties are given an opportunity to reach their own action plan, but, if there is no such agreement, the panel can be reconvened to establish a plan. If an imposed fine is not paid, as under the Labor Side Agreement, NAFTA benefits can be suspended.

Environmental consequences of NAFTA

Environmentalists share many concerns with respect to NAFTA, three of which will be introduced here. First, environmentalists are concerned that NAFTA represents a threat to the sovereignty of the United States because U.S. environmental laws may be challenged under NAFTA. For example, it is feared that the U.S. will not be allowed to refuse entry of goods produced in Mexico even if those goods are produced using production methods that do not meet U.S. environmental, health, or food safety standards. This is based on U.S. experience under the General Agreement on Tariffs and Trade (GATT) when a GATT panel declared that a U.S. embargo on Mexican tuna caught using methods violating the U.S. Marine Mammal Protection Act was illegal. The GATT panel held that products must be treated equally regardless of how they are produced.

Ironically, the first major challenge to national sovereignty came from Canadian corporations. A Canadian conglomerate known as Methanex made use of a little-known section of NAFTA known as Chapter 11 to sue the state of California, demanding financial compensation for loss of market share. Methanex is the world's largest producer of the key ingredient in a **gasoline** additive known as MBTE, a substance that California ordered to be phased out after it began to contaminate public water systems in 1995. A phrase in Chapter 11 written to protect investors from having their property seized by foreign governments has been invoked to justify corporate lawsuits against state and federal environmental regulations. Other examples of cross-border lawsuits include another Canadian company's suit against the state of Mississippi, and a United States corporation's suit against the government of Canada for banning another gasoline additive.

Second, environmentalists label Mexico as a "pollution haven" for U.S. businesses seeking less-stringent enforcement of environmental laws than that which occurs in the United States. Concerns about **environmental degradation** in Mexico due to increased industrialization do seem to be valid. Environmentalists, business leaders, and government officials from the three NAFTA countries agree that environmental contamination had reached serious proportions in northern Mexico in the decades preceding the 1994 effective date of NAFTA. Such contamination continues to spread as Mexico becomes more heavily industrialized under NAFTA. A report published by the CEC in 2002 indicates that chemical producers accounted for the largest amount of pollutants.

On paper, Mexico has environmental laws that parallel many, but not all, of the federal environmental laws of the United States. Mexico's 1988 Código Ecológico, known in English as the "General Ecology Law," is a comprehensive statute addressing **pollution**, resource **conservation**, and

environmental enforcement. Often, however, Mexico's environmental laws are not enforced. This lack of enforcement can be attributed to a variety of reasons. For one thing, the statutes are relatively new, dating only from 1988, and regulations have not been made to supplement the laws. Also, Mexico is a country in which people distrust the legal system and where there are widespread violations of law in various areas (not limited to environmental laws.) Noncompliance with law is accepted and expected in many areas in Mexico. Since Mexico is a developing country striving to implement open, democratic systems of government, this casual attitude toward legislation is a significant hurdle to be overcome throughout Mexican society.

Third, Mexico is a debt-ridden country that continues to struggle with periodic financial crises. Thus, even if Mexico's leaders were convinced that there should be vigorous enforcement of environmental laws and regulations, Mexico lacks money for such enforcement. In connection with its lack of capital, Mexico lacks technology and it lacks infrastructure such as **water treatment** plants, sewage systems, and waste disposal facilities. For example, as of mid-1997, in the entire country of Mexico, there was only one facility licensed for disposal of hazardous wastes. Lacking a place to dispose of toxics and knowing the low **probability** of being cited by government officials for violations, most companies and individuals continue to dump hazardous wastes into Mexico's waters and air and onto its land. Mexico's citizens do not want to live with the contamination any more than we do in the United States. They feel, however, that they are less empowered to "do something about it" than we are as U.S. citizens.

Looking ahead

NAFTA represents a significant turning point in international law, because it recognizes explicitly that trade policy and **environmental policy** are inextricably linked. Through its Environmental Side Agreement, it establishes mechanisms for dealing with citizens' concerns and for dealing with that party or country that systematically fails to enforce its own environmental laws. However, NAFTA's environmental provisions provide only a foundation upon which citizens and governments of the U.S., Mexico, and Canada must build if the environment of North America is to be protected from the often detrimental effects of expanded trade. As of 2002, those detrimental effects have been sufficiently obvious to produce a growing chorus of criticisms of NAFTA. Proposals to create a Free Trade Area of the Americas (FTAA), which would represent an extension of NAFTA's provisions to every country in Central America, South America, and the Caribbean except Cuba, have provoked widespread protest from a variety of environmental and social justice organizations.

North American Water and Power Alliance

Numerous schemes were suggested in the 1960s to accomplish large-scale water transfers between major basins in North America, and one of the best known is the North American Water and Power Alliance (NAWAPA). The plan was devised by the Ralph M. Parson Company of Los Angeles "to divert 36 trillion gallons of water (per year) from the Yukon River in Alaska (through the Great Bear and Great Slave Lakes) southward to 33 states, seven Canadian provinces, and northern Mexico."

The proposed NAWAPA system would bring water in immense quantities from western Canada and Alaska through the plains and **desert** states all the way down to the Rio Grande **watershed** and into the Northern Sonora

and Chihuahua provinces of Mexico. The Rocky Mountain Trench, Peace River, Great Slave Lake, Lesser Slave Lake, North Saskatchewan River, Columbia River, Lake Winnipeg, **Hudson River**, James Bay, and numerous tributaries are part of the proposed NAWAPA feeder system designed to channel water from Canada to Mexico.

A second feeder system in the plan would channel large quantities of water into the western portion of Lake Superior. This influx of water would wash the pollutants dumped into the **Great Lakes** out into the Atlantic Ocean. It would also boost the capacity of the area for generating hydroelectricity.

The NAWAPA plan was also designed to develop hydroelectric plants within northern Quebec and Ontario which would produce power that would be diverted to the United States. The **James Bay hydropower project** in Quebec was completed in the early 1970s. It flooded an area 4,250 mi^2 (11,000 km^2), and 90% of its power goes directly into the Northeastern United States and Ohio. The James Bay II Project in Ontario will eventually incorporate over 80 **dams**, divert three major rivers, and flood traditional Cree land. The majority of its hydroelectric output will also go to the United States.

Proponents of inter-basin transfers tend to focus on the impending water shortages in the western and southwestern United States. In the Great Plains, the **Ogallala Aquifer** is rapidly being depleted. The Black Mesa **water table** is almost exhausted, due to the excessive quantities of water used in mining operations, and California has been consistently unable to meet the needs of both its industries and its population. Supporters of NAWAPA have long argued that this plan is the only way the nation can solve these problems. On February 22, 1965, *Newsweek* hailed the NAWAPA plan as "the greatest, the most colossal, stupendous, supersplendificent public works project in history."

NAWAPA was described as "a monstrous concept—a diabolical thesis" by a former chairperson of the **International Joint Commission**. Much of the opposition to the plan in the 1960s was nationalist rather than environmental in character: The plans were viewed as an attempt to appropriate Canadian resources. Today, many people are asking whether it is necessary or even right to hydrologically re-engineer the ecosystems of North America in order to meet the water needs of the United States. Environmentalists point out that entire ecosystems in many western states have already been disrupted by various water projects. They argue that it is time to investigate other methods, such as **conservation**, which would bring water consumption to levels sustainable by the watersheds of the plains and deserts.

Northern spotted owl

The northern spotted owl (*Strix occidentalis caurina*) is one of three subspecies of the spotted owl (*Strix occidentalis*). Adults are brown, irregularly spotted with white or light brown spots. The face is round with dark brown eyes and a dull yellow colored bill. They are 16–19 in (41–48 cm) long and have wing spans of about 42 in (107 cm). The average weight of a male is 1.2 lb (544 g), whereas the average female weighs 1.4 lb (635 g).

This subspecies of the spotted owl is found only in the southwestern portion of British Columbia, western Washington, western Oregon, and the western coastal region of California south to the San Francisco Bay. Occasionally the bird can be found on the eastern slopes of the Cascade Mountains in Washington and Oregon. It is estimated that there are about 3,000–5,000 individuals of this subspecies.

The other two subspecies of spotted owl are the California spotted owl (*S. o. occidentalis*) found in the coastal ranges and western slopes of the Sierra Nevada mountains from Tehama to San Diego counties, and the Mexican spotted owl (*S. o. lucida*) found from northern Arizona, southeastern Utah, southwestern Colorado, south through western Texas to central Mexico.

It is thought that spotted owls mate for life and are monogamous. Breeding does not occur until the birds are two to three years of age. The typical clutch size is two, but sometimes as many as four eggs are laid in March or early April. The incubation period is 28–32 days. The female performs the task of incubating the eggs while the male bird brings food to the newly-hatched young. The owlets leave the nest for the first time when they are around 32–36 days old. Without fully mature wings, the young are not yet able to fly well and must often climb back to the nest using their talons and beak. Juvenile **survivorship** may be only 11%.

Spotted owls hunt by sitting quietly on elevated perches and diving down swiftly on their prey. They forage during the night and spend most of the day roosting. Mammals make up over 90% of the spotted owl's diet. The most

important prey **species** is the northern flying squirrel (*Glaucomys sabrinus*) which makes up about 50% of the owl's diet. Woodrats and hares also are important. In all, 30 species of mammals, 23 species of birds, two reptile species, and even some invertebrates have been found in the diets of spotted owls.

Northern spotted owls live almost exclusively in very old coniferous forests. They are found in virgin stands of Douglas fir, western hemlock, grand fir, red fir, and areas of **redwoods** that are at least 200 years old. They favor areas that have an old-growth overstory with layers of second-growth understory beneath. The overstory is the preferred nesting site and the owls tend to build their nests in trees that have broken tops or cavities, or on stick platforms. In one study, 64% of the nests were in cavities, and the remainder were on stick platforms or other debris on tree limbs. All of the nests in this study were in conifers, all but two of which were living.

Little is known about what features of a stand are critical for spotted owls. The large trees that have nest sites may be important, particularly those producing a multilayered canopy in which the owls can find a benign **microclimate**. A thick canopy may be critical in sheltering juvenile owls from avian predators, whereas the understory may be important in providing a cool place for the birds to roost during the warm summer months.

Because of this subspecies' dependence on old-growth coniferous forests and because it feeds at the top **trophic level** in the **old-growth forest food chain/web**, it is considered an "indicator species." Indicator species are used by ecologists to measure the health of the **ecosystem**. If the indicator species is endangered, then it is likely that scores of other species in the ecosystem are just as endangered.

The owls are nonmigratory, with dispersal of young being the only regularly observed movement out of established home ranges. The home range size of spotted owls varies from an average of 4,200 acres (1,700 ha) in Washington to about 2,000 acres (800 ha) in California. In 1987, a team of scientists recommended that in order to be reasonably sure of the species' survival that **habitat** for 1,500 pairs be set aside. This would necessitate preserving 4–5 million acres (1.5–2 million ha) of old-growth forests—most of what remains.

Unfortunately for these owls, old-growth forests are a scarce habitat which is commercially valuable for timber. Because of the demand for old-growth timber these birds have been the center of controversy between timber interests and environmentalists. The declining numbers of owls alarm preservationists who want old-growth forests set aside to protect the owls, while the loggers feel it is in the public's best interest to continue to cut the economically valuable old-growth timber. Timber companies claim that 12,000 jobs will be lost along with about $300 million annually if felling is restricted.

Northern spotted owl. (Photograph by John and Karen Hollingsworth. U.S. Fish & Wildlife Service.)

It has been argued that since old-growth forests are being destroyed, these jobs and revenue will be lost eventually anyway. It has also been argued that the U. S. **Forest Service**, which manages most of the remaining old-growth forests, subsidizes the timber industry by building expensive access roads and selling the timber at artificially low prices. Environmentalists suggest that the social costs associated with not cutting old growth could be mitigated by redirecting these monies to retraining programs and income supplements.

In 1990, the northern spotted owl was designated by the U. S. **Fish and Wildlife Service** as a "threatened species." This requires that the owl's habitat be protected from **logging**. Although the decision to list the spotted owl as "threatened" did not affect existing logging contracts, timber companies are trying to avoid compliance with the decision. Specifically, they are trying to persuade the President and Congress to revise the **Endangered Species Act** to allow consideration of economic impacts or to make a specific exception for some or all of the spotted owl's habitat. Currently, under certain circumstances, economic factors can take precedence over biological criteria in deciding whether it is necessary to comply with habitat protection measures.

In these cases a special seven-person interdisciplinary committee can assess the economic impacts of protecting the habitat and circumvent the **Endangered Species** Act if they believe it is warranted. President Bush's Secretary of Interior Manuel Lujan convened the committee to consider allowing logging in spotted owl habitat on some **Bureau of Land Management** lands.

A team of scientists appointed by the federal government to study the situation recommended that the annual harvest on old-growth forests be reduced by 47%. However, former President George Bush rejected this recommendation and instead proposed that harvest be reduced by 21%. This angered both the environmentalists and the timber industry and the two sides became deadlocked. In the meantime, spotted owl policy is being determined by federal judges rather than biologists. For example, it was a court order that forced the U. S. Fish and **Wildlife** Service to identify 11.6 million acres (4.7 million ha) as **critical habitat**. In 1991, a federal judge issued an injunction stopping all new timber sales in areas where the spotted owls live on **national forest** land. The judge also mandated that the Forest Service produce a **conservation** plan and **Environmental Impact Statement** by March 1992. This controversy continued into the presidency of Bill Clinton who convened a Forest Summit in Portland, Oregon on April 2, 1993, to gather information from loggers and environmentalists. Following the summit President Clinton asked his cabinet to devise a balanced solution to the old-growth forest dilemma within 60 days.

Ultimately the fate of the northern spotted owl will be decided in the court rooms and halls of government, where environmentalists and timber interests continue to battle. It is important to realize that the dispute is not merely over one species of owl. The spotted owl is just one of many species dependent on old-growth forests, and may not be in the greatest danger of **extinction**. As an indicator of the prosperity of old-growth ecosystems in the Pacific Northwest, though, its survival means continued health for the entire **biological community**.

Not In My Backyard

NIMBY is an acronym for "Not In My Backyard" and is often heard in discussions of **waste management**. While every community needs a site for waste disposal, frequently no one wants it near his or her home. In the early part of this century, in fact, up until the early 1970s, the town dump was a smelly, rodent-infested place that caught fire on occasion. Loose debris from these facilities would also blow onto adjacent property. Citizens were justified in their aversion to landfills because **hazardous waste** and **chemicals** were often dumped into landfills, which contaminated **groundwater** and surface water. After the passage of the **Resource Conservation and Recovery Act** (RCRA) in 1976, many of these facilities were closed and dumps converted into sanitary landfills that required daily cover, fencing, leachate collection systems, and other design elements that made them much better neighbors. Still, many citizens refused to have landfills close to their homes.

In addition to landfills, citizens are also concerned about having other waste management facilities near them. Large open air **composting** facilities are not popular because of the odor they produce. A materials **recycling** facility (MRF) is not always a desirable neighbor because of the noise it generate.

Despite assurances by experts of the improvements and safety of modern waste management facilities, communities continue to be wary of them. In order to overcome the NIMBY attitude, professionals in the waste management field must collaborate with communities so that citizens gain understanding and ownership of **solid waste** management problems. The problem of waste is generated at the community level so the solution must be generated at the community level. With sensible planning and patience there may be less NIMBY-mentality in the future.

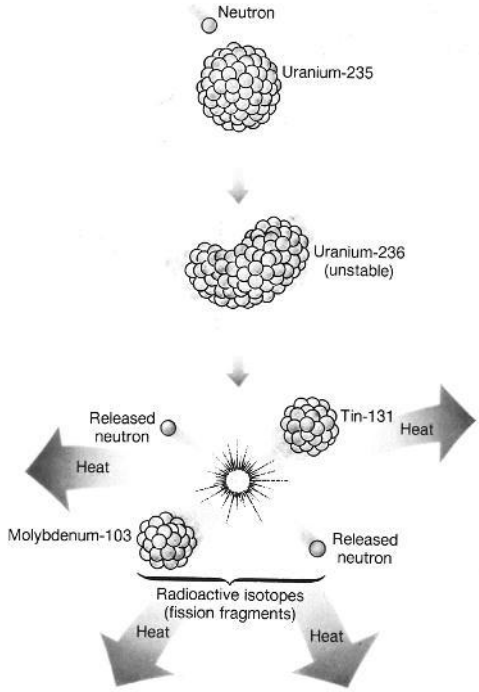
Nuclear fission

When a **neutron** strikes the nucleus of certain isotopes, the nucleus breaks apart into two roughly equal parts in a process known as nuclear fission. The two parts into which the nucleus splits are called fission products. In addition to fission products, one or more neutrons is also produced. The fission process also results in the release of large amounts of energy.

The release of neutrons during fission makes possible a **chain reaction**. That is, the particle needed to initiate a fission reaction—the neutron—is also produced as a result of the reaction. Each neutron produced in a fission reaction has the potential for initiating one other fission reaction. Since the average number of neutrons released in any one fission reaction is about 2.3, the rate of fission in a block of material increases rapidly.



A chain reaction will occur in a block of fissionable material as long as neutrons (1) do not escape from the block and (2) are not captured by nonfissionable materials in the block. Two steps in making fission commercially possible, then, are (1) obtaining a block of fissionable material large enough to sustain a chain reaction—the critical size—and (2) increasing the ratio of fissionable to nonfissionable material in the block—enriching the material.

Atomic bombs, developed in the 1940s, obtain all of their energy from fission reactions while **hydrogen** bombs use fission reactions to trigger **nuclear fusion**. A long-term environmental problem accompanying the use of these weapons is their release of radioactive fission products during detonation.

The energy available from fission reactions is far greater, pound for pound, than can be obtained from the **combustion** of **fossil fuels**. This fact has made fission reactions highly desirable as a source of energy in weapons and in power production.

Many experts in the post-World War II years argued for a massive investment in nuclear **power plants**. Such plants were touted as safe, reliable, nonpolluting sources of energy. When operating properly, they release none of the pollutants that accompany power generation in fossil fuel plants. By the 1970s, more than a hundred **nuclear power** plants were in operation in the United States.

Then, questions began to arise about the safety of nuclear power plants. These concerns reached a peak when

The process of nuclear fission as carried out in the core of a nuclear reactor. A neutron strikes the unstable isotope Uranium-235. This isotope absorbs the neutron and splits or fissions into tin-131 and molybdenum-103. Two or three neutrons are released per fission event and continue the chain reaction. The reaction product has a total mass slightly less than the starting material with the residual mass converted into energy (primarily heat). (McGraw-Hill Inc. Reproduced by permission.)

the cooling water system failed at the **Three Mile Island Nuclear Reactor** at Harrisburg, Pennsylvania, in March 1979. That accident resulted in at least a temporary halt in nuclear power plant construction in the United States. No new plants have been authorized since that time. A much more serious accident occurred at Chernobyl, Ukraine, in 1986 when one of four reactors on the site exploded, spreading a cloud of radioactive material over parts of the USSR, Poland, and northern Europe.

Perhaps the most serious environmental concern about fission reactions relates to fission products. The longer a fission reaction continues, the more fission products accumulate. These fission products are all radioactive, some with short half lives, other with longer half lives. The former can be stored in isolation for a few years until their **radioactivity** has reduced to a safe level. The latter, however, may remain hazardous for hundreds or thousands of years. As of the early 1990s, no completely satisfactory method for storing

these nuclear wastes had been developed. *See also* Nuclear fusion; Nuclear weapons; Radiation exposure; Radioactive pollution; Radioactive waste; Radioactive waste management; Radioactivity

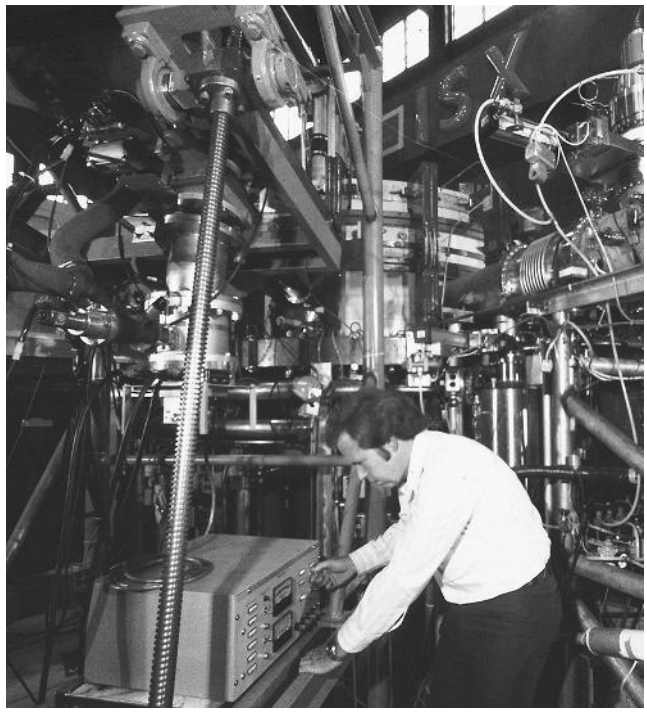
Nuclear fusion

The process by which stars produce energy has always been of great interest to scientists. Not only would the answer to that puzzle be of value to astronomers, but it might also suggest a method by which energy could be generated for human use on earth.



In 1938, German-American physicist Hans Bethe suggested a method by which **solar energy** might be produced. According to Bethe's hypothesis, four **hydrogen** atoms come together and fuse—join together—to produce a helium atom. In the process, very large amounts of energy are released.

This process is not a simple one, but one that requires a series of changes. In the first step, two hydrogen atoms fuse to form an atom of deuterium, or "heavy" hydrogen. In later steps, hydrogen atoms are regenerated, providing the materials needed to start the process over again. Like **nuclear fission**, then, nuclear fusion is a **chain reaction**.

Since Bethe's original research, scientists have discovered other fusion reactions. One of these was used in the first practical demonstration of fusion on earth, the "hydrogen" bomb. It involved the fusion of two hydrogen isotopes, deuterium and tritium.

Nuclear fusion reactions pose a difficult problem. Fusing isotopes of hydrogen requires that two particles with like electrical charges be forced together. Overcoming the electrical repulsion of these two particles requires the initial input into a fusion reaction of very large amounts of energy. In practice, this means heating the materials to be fused to very high temperatures, a few tens of millions of degrees Celsius. Because of these very high temperatures, fusion reactions are also known as thermonuclear reactions.

Temperatures of a few millions of degrees Celsius are common in the center of stars, so nuclear fusion can easily be imagined there. On earth, the easiest way to obtain such temperatures is to explode a fission (atomic) bomb. That explosion momentarily produces temperatures of a few tens of millions of degrees Celsius. A fusion weapon such as a hydrogen bomb consists, therefore, of nothing other than a fission bomb surrounded by a mass of hydrogen isotopes.

Tokamak nuclear fusion reactor in Oak Ridge, Tennessee. (Phototake. Reproduced by permission.)

As with nuclear fission, there is a strong motivation to find ways of controlling nuclear fusion reactions so that they can be used for the production of power. This research, however, has been hampered by some extremely difficult technical challenges. Obviously, no ordinary construction material can withstand the temperatures of the hot, gaseous-like material, or **plasma**, involved in a fusion reaction. Efforts have been aimed, therefore, at finding ways of containing the reaction with a magnetic field. The tokamak reactor, originally developed by Russian scientists, appears to be one of the most promising methods of solving this problem.

Research on controlled fusion has been a slow, but continuous, progress. Some researchers are confident that a solution is close at hand. Others doubt the possibility of bringing nuclear fusion under human control. All agree, however, that successful completion of this research could provide humans with perhaps the "final solution" to their energy needs.

Nuclear power

When nuclear reactions were first discovered in the 1930s, many scientists doubted they would ever have any practical application. But the successful initiation of the first controlled reaction at the University of Chicago in 1942 quickly changed their views.

In the first controlled nuclear reaction, scientists discovered a source of energy greater than anyone had previously imagined possible. They discovered that the nuclei of **uranium** isotopes could be split, thus releasing tremendous energy. The reaction occurred when the nuclei of certain isotopes of uranium were struck and split by neutrons. This is now known as **nuclear fission**, and the fission reaction results in the formation of three types of products: energy, neutrons, and smaller nuclei about half the size of the original uranium nucleus.

Neutrons are actually produced in a fission reaction, and this fact is critical for energy production. The release of neutrons in a fission reaction means that the particles required to initiate fission are also a product of the reaction. Once initiated in a block of uranium, fission occurs over and over again, in a **chain reaction**. Calculations done during these early discoveries showed that the amount of energy released in each fission reaction is many times greater than that released by the chemical reactions that occur during a conventional chemical explosion.

The possibility to release such high energies with nuclear reactions was used in the development of the atomic bomb. After the dropping of this bomb brought World War II to an end, scientists began researching the harnessing of nuclear energy for other applications, primarily the generation of electricity. In developing the first **nuclear weapons**, scientists only needed to find a way to initiate nuclear fission—there was no need to control it once it had begun. In developing the peacetime application of nuclear power however, the primary challenge was to develop a mechanism for keeping the reaction under control once it had begun so that the energy released could be managed and used. This is the main purpose of nuclear power plants—controlling and converting the energy produced by nuclear reactions.

There are many types of nuclear **power plants**, but all plants have a reactor core and every core consists of three elements. First, the fuel rods; these are long, narrow, cylindrical tubes that hold small pellets of some fissionable material. At present only two such materials are in practical use, uranium-235 and plutonium-239. The uranium used for nuclear fission is known as enriched uranium, because it is actually a mixture of uranium-235 with uranium-238. Uranium-238 is not fissile and the required chain reaction will not occur if the fraction of uranium-235 present is not at least 3%.

The second component of a reactor core is the moderator. Only slow-moving neutrons are capable of initiating nuclear fission, but the neutrons produced as a result of nuclear fission are fast-moving. These neutrons move too fast to initiate other reactions, thus moderators are used to slow them down. Two of the most common moderators are graphite (pure **carbon**) and water.

The third component of a reactor core is the control rods. In operating a nuclear power plant safely and efficiently, it is of the utmost importance to have exactly the right amount of neutrons in the reactor core. If there are too few, the chain reaction comes to an end and energy ceases to be produced. If there are too many, fission occurs too quickly, too much energy is released all at once, and the rate of reaction increases until it can no longer be controlled or contained. Control rods decrease the number of neutrons in the core because they are made of a material that has a strong tendency to absorb neutrons. **Cadmium** and boron are materials that are both commonly used. The rods are mounted on pulleys allowing them to be raised or lowered into the reactor core as need may be. When the rods are fully inserted, most of the neutrons in the core are absorbed and relatively few are available to initiate a chain reaction. As the rods are withdrawn from the core, more and more neutrons are available to initiate fission reactions. The reactions reach a point where the number of neutrons produced in the core is almost exactly equal to the number being used to start fission reactions, and it is then that a controlled chain reaction occurs.

The heat energy produced in a reactor core is used to boil water and make steam, which is then used to operate a turbine and generate electricity. The various types of nuclear power plants differ primarily in the way in which heat from the core is used to do this. The most direct approach is to surround the core with a huge tank of water, some of which can be boiled directly by heat from the core. One problem with boiling-water reactors is that the steam produced can be contaminated with radioactive materials. Special precautions must be taken with these reactors to prevent contaminated

steam from being released into the **environment**. A second type of nuclear reactor makes use of a heat exchanger. Water around the reactor core is heated and pumped to a heat exchange unit, where this water is used to boil water in an external system. The steam produced in this exchange is then used to operate the turbine and generator.

There is also a type of nuclear reactor known as a breeder, or fast-spectrum reactor because it not only produces energy but also generates more fuel in the form of plutonium-239. In conventional reactors, water is used as a coolant as well as a moderator, but in breeder reactors the coolant used is sodium. Neutrons have to be moving quickly to produce **plutonium**, and sodium does not moderate their speed as much as water does. Another design, the CANDU reactor, (acronym for CANada Deuterium Uranium) uses deuterium oxide (heavy water) as moderator and natural uranium as fuel. With the uranium fuel surrounded by heavy water, chain reaction fission takes place, releasing energy in the form of heat. The heat is transferred to a second heavy water system pumped at high pressure through the tubes to steam generators, from which the heat is transferred to ordinary water which boils to become the steam that drives the turbine generator.

Nuclear power plants could never explode with the power of an atomic bomb, because the quantity of uranium-235 required is never present in the reactor core. However, they do pose a number of well-known safety hazards. From the very beginning of the development of nuclear reactors, safety was an important consideration as scientists and engineers tried to anticipate the dangers associated with nuclear reactions and radioactive materials. Thus, control rods were developed to prevent the fission reactions from generating too much heat. The reactor and its cooling system are always enclosed in a containment shell made of thick sheets of steel to prevent the escape of radioactive materials. Nuclear power plants are highly complex facilities, with back-up systems for increased safety which are themselves supported by other back-up systems. But the components of these systems age, and human errors can and do occur; safety measures do not always function the way there were designed.

On December 2, 1957, the first nuclear power plant opened in Shippingport, Pennsylvania, and to many the nuclear age seemed to have begun. Over the next two decades, more than 50 plants were commissioned, with dozens more ordered. But safety problems plagued the industry. An experimental reactor in Idaho Falls, Idaho, had already experienced a partial meltdown as a result of operator error in 1955. In October 1957, just months before the Shippingport plant came on line, a production reactor near Liverpool, England, caught fire, releasing radiation over Great Britain and northern Europe.

The most critical event in the history of nuclear power in the United States was the accident at the **Three Mile Island nuclear reactor** near Harrisburg, Pennsylvania. In March 1979, fission reactions in the reactor core went out of control, generating huge amounts of heat, and a meltdown resulted. Fuel rods and the control rods were melted; the cooling water was turned to steam and the containment structure itself was threatened. No new plants have been ordered in the United States since this accident, and 65 plants on order at that time were cancelled. The explosion at the Chernobyl reactor near Kiev, Ukraine, dealt a second blow to the industry.

Even without these accidents, another problem with nuclear power would remain. This is the problem of spent radioactive wastes. About a third of the 10 million fuel pellets used in any reactor core must be removed each year because they have been so contaminated with fission by-products that they no longer function efficiently. These highly radioactive pellets must be disposed of in a safe fashion, but 50 years after the first controlled reaction, no method has yet been discovered to address this issue. Today, these wastes are most commonly stored on a temporary basis at or near the power plant itself. Many have argued that further development of nuclear power should not even be considered until better methods for **radioactive waste management** have been developed.

The International Nuclear Safety Center (INSC), which operates under the guidance of the Director of International Nuclear Safety and Cooperation in the **U.S. Department of Energy** (DOE), has the mission of improving nuclear power reactor safety worldwide. The INSC is dedicated to developing improved nuclear safety technology and promoting the open exchange of nuclear safety information among nations, sponsoring scientific research activities as collaborations between the U.S. and its international partners. Safety issues are addressed at several levels, including: **risk assessment**, containment, structural integrity of reactors, assessment of their seismic reliability, equipment operability, fire protection, and reactor safeguards.

The security of nuclear facilities has also been a point of growing concern. In 1991, the NRC instituted an Operational Safeguards Response Evaluation (OSRE) program, which evaluated the ability of nuclear facility security personnel to withstand a staged commando-style attack by intruders. Unfortunately, six of the 11 evaluations performed in 2000 and 2001 resulted in the "attackers" being able to penetrate security and simulate damage to reactor equipment.

In the post-September 11 terrorist attack environment, the vulnerability of America's 104 nuclear power facilities are a critical national security concern. All nuclear facilities were placed on high alert immediately following the attacks,

Nuclear power plants are a peacetime application of energy initiated through nuclear fission. (Photograph by Robert J. Huffman. Field Mark Publications. Reproduced by permission.)

and in early 2002 the **Nuclear Regulatory Commission** (NRC) issued interim confidential security orders for all licensees to comply with. In addition, decommissioned nuclear plants and spent fuel storage facilities were also required to implement the security orders. The NRC also conducted a thorough review of its Internet web site, taking the site offline temporarily to analyze content and remove all documents deemed sensitive to national security. In April 2002, the NRC announced the establishment of a dedicated department for plant security, the Office of Nuclear Security and Incident Response.

The future role of nuclear power in energy production throughout the world is uncertain. But the current absence of nuclear power plant development in the United States should not be taken as indicative of future trends, as well as trends in the rest of world. France, for example, obtains more than half of its electricity from nuclear power, despite the safety problems. And many believe that nuclear power should be an important part of energy production in the United States as well. Proponents of nuclear power argue that its dangers have been greatly exaggerated in this country. The risks, they argue, must be compared with the health and environmental hazards of other fuels, particularly **fossil fuels**.

In 1999, the U.S. Department of Energy announced a new initiative called Generation IV. Designed to generate interest and scientific research in nuclear power advances, the program set out the following goals for the next generation (i.e., generation IV) of nuclear power plants: 1) highly economical; 2) enhanced safety; 3) sustainable with minimal waste; and 4) commercially viable by 2025. Ten countries, including the United States, United Kingdom, Canada, South Africa, and Japan, were participating in the Generation IV International Forum (GIF) as of early 2002. One of the most promising prototypes reactor designers have come up with is the gas-cooled pebble-bed reactor, which uses a non-reactive helium coolant and operates more efficiently and at less cost than current water-cooled systems.

For some, hope for the future of nuclear power rests with the development of **nuclear fusion**. A nuclear power plant based on a fusion reaction would amount to a controlled

version of a **hydrogen** bomb, just as conventional nuclear plants are equivalent to a controlled version of an atomic bomb. But the problem of managing the reaction is far more difficult with fusion than it is with fission, and scientists have been working on this issue unsuccessfully for more than 40 years. Some believe that a fusion power plant could become a reality in the next century, but many now doubt that such a plant will ever be feasible.

Nuclear Regulatory Commission

The development of **nuclear weapons** during World War II raised a number of difficult nonmilitary questions for the United States. Most scientists and many politicians realized that the technology used in weapons research had the potential for use in a variety of peacetime applications. In fact, research on techniques for controlling **nuclear fission** for the production of electricity was well under way before the end of the war.

An intense Congressional debate over the regulation commercial **nuclear power** resulted in the creation in 1946 of the **Atomic Energy Commission** (AEC). The AEC had two major functions: to support and promote the development of nuclear power in the United States and to monitor and regulate the applications of nuclear power.

Some critics pointed out early on that these two functions were inherently in conflict. How could the AEC act as a vigorous protector of the public safety, they asked, if it also had to encourage industry growth? The validity of that argument did not become totally obvious for nearly two decades. It was not until the early 1970s that the suppression of information about safety hazards from existing plants by the AEC became public knowledge.

The release of this information prompted Congress and the President to rethink the government's role in nuclear power issues. The result of that process was the **Energy Reorganization Act** of 1973 and Executive Order 11834 of January 15, 1975. These two actions established two new governmental agencies, the Nuclear Regulatory Commission (NRC) and the Energy Research and Development Agency (ERDA). NRC was assigned all of AEC's old regulatory responsibilities, while ERDA assumed its energy development functions.

The mission of the Nuclear Regulatory Commission is to ensure that the civilian uses of nuclear materials and facilities are conducted in a manner consistent with public health and safety, environmental quality, national security, and anti-trust laws. The single most important task of the commission is to regulate the use of nuclear energy in the generation of electric power.

In order to carry out this mission, the commission has a number of specific functions. It is responsible for inspecting and licensing every aspect of nuclear power plant construction and operation, from initial plans through actual construction and operation to disposal of **radioactive waste** materials. The commission also contracts for research on issues involving the commercial use of nuclear power and holds public hearings on any topics involving the use of nuclear power. An important ongoing NRC effort is to establish safety standards for nuclear **radiation exposure**.

A fair amount of criticism is still directed at the Nuclear Regulatory Commission. Critics feel that the NRC has not been an effective watchdog for the public in the area of nuclear safety. For example, the investigation of the 1979 **Three Mile Island Nuclear Reactor** accident found that the commission was either unaware of existing safety problems at the plant or failed to inform the public adequately about these problems.

Nuclear test ban

The Comprehensive Test Ban Treaty (CTBT), which prohibits all nuclear explosions either for military or "peaceful" purposes, was adopted by the United Nations General Assembly in September 1996. Although disputes remain in some countries over the ratification of the treaty, the adoption of the text by the General Assembly marks the culmination of several decades of intermittent negotiation aimed at the worldwide prohibition of nuclear explosions within the United Nations nuclear nonproliferation framework. The CTBT aims at preventing the development and proliferation of **nuclear weapons** and is viewed by the United Nations as an important step toward eventual nuclear disarmament.

President Dwight D. Eisenhower first suggested a ban on atmospheric testing in 1955, but it was not until August 1963, in the aftermath of the 1962 superpower showdown over the stationing of nuclear-capable missiles in Cuba, that the United States and the U.S.S.R. agreed to a Partial Test Ban Treaty (PTBT). This agreement banned all atmospheric tests of nuclear weapons, but allowed both parties to set off explosions in the more frequently-used underground tests. With both superpowers concerned about issues of sovereignty and espionage, the PTBT limited procedures for verification of compliance to what were called "national technical means," which consisted mainly of satellite, communications, and long-distance seismic monitoring. While the PTBT's overall impact on arms control is generally thought to have been negligible, it did serve to prevent a great deal of **pollution** of the **atmosphere** and the Earth's surface by **plutonium** and other radioactive substances.

In 1974, the PTBT was supplemented by the signing of a Threshold Test Ban Treaty (TTBT) that limited the explosive yield of underground nuclear tests. Initially, the TTBT also relied on national technical means for verification. But in 1990, the original protocol was replaced with a new agreement on verification means that allowed for on-site inspections and in-country seismic monitoring.

Fourteen years after the adoption of the PTBT, the United States, U.S.S.R., and United Kingdom convened trilateral talks aimed at achieving a comprehensive test ban. Some limited progress was made toward resolving several points of disagreement, but in general the parties achieved few tangible results in these negotiations. This lack of success combined with a general toughening of United States policy towards the U.S.S.R. after the 1980 elections to all but end discussion of a test ban treaty.

Against the wishes of both the United States and the United Kingdom, a series of amendments was suggested in January 1991, under the authority of the existing treaties' revision procedures. A conference of the nuclear powers was convened to consider the proposed amendments. These negotiations were inconclusive, but they did signal considerable international interest in a comprehensive ban. Political momentum toward this end was given a boost in 1992, when Russia, France, and the United States declared a nine-month moratorium on all testing. In doing so, the United States reversed official doctrine introduced in the 1980s, which held that testing via explosions was a necessary component of national security. The radical geopolitical changes associated with the disintegration of the U.S.S.R. also played a role in changing the climate of negotiations. As a result, the 1994 Conference on Disarmament created a committee with a mandate to establish a framework for a comprehensive ban. By extending its own moratorium on nuclear tests, the Clinton Administration signaled its willingness to sign the resulting CTBT, giving the final process of negotiation an important boost.

Technological and political developments, however, are already raising new issues for arms control experts and negotiators. Advances in communications and surveillance technology aid the verification of compliance. But advances in nuclear physics and weapons technology, such as the advent of so-called micro-nukes and hydronuclear tests with greatly reduced yields, make the very definition of nuclear testing problematic. Several countries, especially India and Pakistan, have expressed strong misgivings about the CTBT. Although the United States strongly supports the treaty on an official level, substantial and deep-rooted opposition to the CTBT persists, including some notable critics among those charged with oversight of its huge nuclear arsenal. Opponents of the treaty argue that limited testing is necessary for checking the safety and reliability of existing nuclear warheads and for maintaining the credibility of the nuclear deterrent.

Nuclear weapons

There are two types of nuclear weapons, each of which utilizes a different nuclear reaction: **nuclear fission** and **nuclear fusion**. The bomb developed by the Manhattan Project and dropped on Japan during World War II were fission weapons, also known as atomic bombs. **Hydrogen** bombs are fusion weapons, and these were first developed and produced during the early 1950s.

In fission weapons, the explosive energy is derived from nuclear fission, in which large atomic nuclei are split into two roughly equal parts. Every time a nucleus divides,

it releases a large amount of energy. Each fission reaction also produces one or more neutrons, the subatomic particles that are needed to initiate a fission reaction. Thus, once a fission reaction has been started in a few nuclei, it rapidly spreads to other nuclei around it, creating a **chain reaction**. The two nuclei most commonly used for this type of nuclear reaction are uranium-235 and plutonium-239.

The necessary fission reaction will not occur if an atomic bomb carries any single piece of fissionable material that is more than a few kilograms. The bomb can contain more than one piece of this size, but it seldom contains more than three or four. Thus there is a limit to the size of a fission weapon, as well as the energy it can release. Nuclear weapons and the force of their blasts are measured in kilotons, each of which is equivalent to a thousand tons of TNT. Fission weapons are limited to 20 or 30 kilotons.

Fusion weapons derive their explosive power from a reaction that is the opposite of fission. In fusion, two small nuclei combine or fuse, releasing large amounts of energy in the process. The materials needed to initiate another fusion reaction are produced as a byproduct. Fusion, like fission, is a cyclic reaction.

In contrast to fission weapons, a hydrogen bomb can be of almost any size. Such a bomb consists of a fission bomb at the core, surrounded by a mass of hydrogen isotopes used in the fusion reactions. No limit exists to the mass of hydrogen that can be used, and there is thus no theoretical limit to the size of fusion weapons. The practical limit is simply the necessity of transporting it to a target; the bomb cannot be so large that a rocket or an airplane is unable to carry it effectively. Both fission and fusion weapons are often classified as strategic or tactical. Strategic weapons are long-range weapons intended primarily for attack on enemy land. Tactical weapons are designed for use on the battlefield, and their destructive power is adjusted for their shorter range.

Nuclear weapons cause destruction in a number of different ways. They create temperatures upon explosion that are, at least initially, millions of degrees hot. Some of their first effects are heat effects, and materials are often incinerated on contact. The heat from the blast also causes rapid expansion of air, resulting in very high winds that can blow over buildings and other structures. A weapon blast also releases high levels of radiation, such as neutrons, x rays, and gamma rays. Humans and other animals close to the center of the blast suffer illness and death from **radiation exposure**. The set of symptoms associated with such exposure is known as **radiation sickness**. Many individuals who survive radiation sickness eventually develop **cancer** and their offspring frequently suffer genetic damage. Finally, a weapon's blast releases huge amounts of radioactive materials. Some of these materials settle out of the **atmosphere** almost immediately, creating widespread contamination. Others remain in the atmosphere for weeks or months, resulting in long-term **radioactive fallout**.

Because of their destructive power, the nations of the world have been trying for many years to reach agreements on limiting the manufacture and possession of nuclear weapons. Between July 16, 1945, and September 23, 1992, the United States of America conducted (by official count) 1054 nuclear tests, and two nuclear attacks. In 1963, the United States and the former Soviet Union agreed to a Limited Nuclear Test Ban Treaty that banned explosions in the atmosphere, outer space, and underwater. After 1963, both nations continued testing underground. The 1974 Threshold Test Ban Treaty restricted the underground testing of nuclear weapons by the United States and the former Soviet Union to yields no greater than 150 kilotons.

In the 1980s and 1990s, debates over arms control and continued testing of nuclear weapons were affected by a number of international developments. The first was the growing internal weakness and eventual disintegration of the former Soviet Union. After a decade of difficult negotiations, the United States and the Soviet Union signed a bilateral Strategic Arms Reduction Agreement, or START I, on July 31, 1991. Five months later the Soviet Union dissolved. It was succeeded by four states that had nuclear weapons on their territories: Russia, the Ukraine, Belarus, and Kazakhstan. On December 5, 2001, the United States and the Russian Federation succeeded in reducing their number of deployed warheads to the level specified by START I. The Ukraine, Belarus, and Kazakhstan have eliminated or removed from their territory all nuclear weapons left over from the Soviet period. The START II treaty, which specifies further reductions in the number of nuclear weapons possessed by both powers, was ratified by the U.S. Senate on January 26, 1996, and by the Russian Duma on April 14, 2000. On May 24, 2002, President George W. Bush of the United States and President Vladimir Putin of Russia signed the Strategic Offensive Reductions Treaty, which commits both nations to reduce the number of their nuclear warheads to two-thirds of their 2002 levels by December 31, 2012.

The second international development of concern has been the steady increase in the number of states possessing nuclear weapons, and the potential for their use in international conflicts. As of the spring of 2002, the Carnegie Institute's Non-Proliferation Project estimates that 35 nations have some type of nuclear ballistic missile. It is difficult to obtain precise information about the number and location of these weapons because many countries in the so-called "nuclear club" have not openly acknowledged their membership.

The third development since the 1980s is the growing possibility that terrorist groups might acquire the informa-

tion and materials to build nuclear devices. This fear acquired new prominence after the terrorist attacks of September 11, 2001. As early as 1997 Alexander Lebed, a Russian general, claimed that the former Soviet Union had developed nuclear weapons small enough to fit in a suitcase. Although technical information is lacking on the Russian side, the United States' experimental development of small-sized nuclear weapons suggests that it is technically possible to design a bomb small enough to fit in a large suitcase. In addition, it is known that members of al-Qaeda made several attempts to purchase commercial reactor-grade **plutonium** during the 1990s. As of 2002, however, the likelihood of a terrorist group's constructing a small portable nuclear device is not high. The construction of a suitcase bomb using plutonium would require a very high degree of sophistication, and would be extremely hazardous to its creators. On the other hand, there are no substantial technical obstacles for a small terrorist group to manufacture a simple but highly destructive nuclear bomb about the size of a truck. One scientific expert has stated, "There is no doubt that if a group like al-Qaeda were to obtain sufficient fissile material—no more than 12 kg of plutonium, or 50 kg of highly enriched **uranium**, and quite possibly less—a highly destructive [nuclear] bomb could be constructed."

Nuclear winter

Nuclear winter is a term given to what would happen to Earth's **environment** following a large-scale nuclear war. In effect, the entire planet would be plunged into a very bitter winter that would last months or years. The most severe consequence would be that Earth's **climate** would become too cold to grow vital food crops, including rice, wheat, and corn. It would likely lead to the starvation of hundreds of millions of people who survived the initial nuclear blasts. In effect, it would likely be the end of civilization.

However, with the end of the Cold War and the breakup of the Soviet Union, the threat of a full-scale nuclear exchange between the United States and Russia has greatly diminished. Today, the term nuclear winter is also used to describe the aftermath of any event that sends huge amounts of **particulate** matter into the **atmosphere**, blocking the sun and drastically cooling Earth's atmosphere. Such events could include the simultaneous eruption of a number of large volcanoes, or the impact upon the planet of a large comet or asteroid.

Although eight countries are known to possess **nuclear weapons** as of 2002, it was the thousands of warheads held by the United States and Russia that most worried scientists during the Cold War. A nuclear exchange between other countries, such as India and Pakistan, would not create a nuclear winter because most of the world's croplands would be spared.

Many of the horrible consequences of a global nuclear conflict have been well known for nearly half a century. Though much research has been conducted in this area, there is still much to be learned. Many scientists believe that the **smoke** produced as a result of a nuclear conflict would reduce the transmission of sunlight to Earth's surface over a significant portion of the planet. According to the theory, this reduction in sunlight would then cause a cooling on land surfaces of anywhere from 18–65°F (10–35°C). Interior parts of a continent would experience greater cooling than would coastal regions. Some parts of the planet that now experience a temperate climate might be plunged into winter-like conditions.

The idea of nuclear winter has been controversial ever since it was first proposed in 1983 by famed astronomer Carl Sagan (1934–1996). The U.S. **National Academy of Sciences**, the U.S. Office of Science and Technology Policy, the World Meteorological Organization, the International Council of Scientific Unions, and the **Scientific Committee on Problems of the Environment**, as well as dozens of

individual scientists, have analyzed the potential for a nuclear winter and the problems that it might engender. These studies have not resolved the many issues surrounding a possible nuclear winter effect, but they have clarified a number of factors involved in that effect.

First, the fundamental logic behind a possible nuclear winter effect has been considerably strengthened. Experts estimate that about 9,000 teragrams (9 trillion grams) of finished lumber exist in the world. A large portion of that is found in urban areas that are likely to be the focus of a nuclear attack. By one estimate, anywhere from 25–75% of the wood in an urban area would be ignited in a nuclear attack. A second resource vulnerable to nuclear attack is the world's **petroleum** reserves. Most experts agree that oil refineries, oil storage centers, and other concentrations of oil deposits would be likely targets in a nuclear attack. These materials would also serve as fuel in a widespread fire storm.

The main product of concern in the **combustion** of wood, petroleum, and other materials (**plastics**, tar, asphalt, vegetation, etc.) would be sooty smoke. This smoke would decrease solar radiation by as much as 50%. In addition, it would not easily be washed out of the atmosphere by rain, snow, and other forms of precipitation. Computer models have also shown that soot in the atmosphere may be more stable than first imagined. Studies also suggest that a nuclear winter effect could produce serious consequences for the **ozone** layer. One effect would be the dislocation of the ozone layer over the Northern Hemisphere towards the Southern Hemisphere. Another effect would involve actual destruction of the ozone layer by **nitrogen** oxide molecules carried aloft by smoke.

Scientists have studied a number of natural phenomena with nuclear winter-like effects. Volcanic eruptions, massive forest fires, natural dust clouds, urban fires, and extensive wild fires all produce massive amounts of smoke similar to what would be expected in a nuclear conflict. For example, massive wildfires in China during May of 1987 were found to reduce daytime temperatures in Alaska by 4–12°F (2–6°C) in ensuing months. Possible climatic effects from the enormous oil well fires during the **Persian Gulf War**, as well as recent volcanic eruptions, are also being studied. One scientist studying this phenomenon has said, however, that "severe environmental anomalies—possible leading to more human casualties globally than the direct effects of nuclear war—would be not just a remote possibility, but a likely outcome."

A number of scientists have challenged Sagan's findings, saying he overestimated the devastation that would result from a large-scale nuclear war. Several scientists suggested the result of such a war would be a "nuclear fall" rather than nuclear winter. While this would also be a disaster, the scientists suggested that it would not mean the end of civilization as Sagan predicted. The scientists explained that this is because Sagan greatly overestimated both the amount of smoke and dust that would be created and its duration in the atmosphere.

Nucleic acid

Nucleic acids are macromolecules composed of polymerized nucleotides. Nucleotides, in turn, are structured of phosphoric **acid**, pentose sugars, and organic bases. Deoxyribonucleic acid (DNA) most commonly exists as a double stranded helix. The genetic information of some viruses, bacteria, and all higher organisms is encoded in DNA, and the physical basis of heredity of these organisms is dependent upon the molecular structure of DNA.

DNA is transcribed into single stranded **ribonucleic acid** (RNA), which is then translated into protein. The conversion of the genetic information of a **species** into the fabric of that organism involves several kinds of RNA, *viz.*, messenger RNA (mRNA), transfer RNAs (tRNA), and ribosomal RNAs (rRNA). The genetic material of some viruses is RNA.

Nutrient

All plants and animals require certain **chemicals** for growth and survival. These chemicals are called biogenic salts or nutrients (from the Latin word *nutrio* meaning to feed, rear, or nourish). They can be categorized as those needed in large amounts called macronutrients, and those needed in

minute amounts called micronutrients or trace elements. Macronutrients include **nitrogen** (an essential building block of chlorophyll and protein), **phosphorus** (used to make DNA and ATP), calcium (a component of cell walls and bones), sulfur (a component of amino acids), and magnesium (a component of bones and chlorophyll). Micronutrients, although needed only in trace amounts, are still essential for survival. Examples include cobalt (used in the synthesis of vitamin B_{12}), iron (essential for **photosynthesis** and blood respiratory pigment), and sodium (used in the maintenance of proper acid-based balance called osmoregulation, nerve transmission, and several other functions). Some micronutrients, such as **copper** and zinc, can be harmful in large amounts. The borderline between necessary and excessive is often narrow and varies among **species**.

Oak Ridge, Tennessee

Along with towns such as Los Alamos, New Mexico, and the area around the Savannah River in Georgia, Oak Ridge is central to the history of the development of **nuclear weapons** in the United States. It has also come to represent many of the environmental consequences of nuclear research and weapons production.

Oak Ridge was a small, sleepy town when it was selected as a research site in the 1940s for the development of the atomic bomb. Amidst an **atmosphere** of intense secrecy, the government built the Oak Ridge National Laboratories within a period of months and assembled a force of 75,000 scientists. These physicists, engineers, and others worked under extreme security to design various components of the **hydrogen** bomb. Their research was carried out under the auspices of the Manhattan Project, though the tasks were compartmentalized and few scientists are thought to have been aware of the larger significance of their work.

After the end of World War II, the laboratories at Oak Ridge were used for the research activities and weapons production of the Cold War. Although the area did experience decreases in the number of highly trained personnel, the research center remained an important part of the government's network of national laboratories. During this period, the **U.S. Department of Energy** (DOE) took over the management of the Oak Ridge laboratories and subcontracted administrative operations to such private corporations as Union Carbide and the Martin Marietta Corporation. Peacetime activities also included major research and educational initiatives developed in association with the local university.

Because of the urgency and secrecy under which military research was conducted at Oak Ridge, little attention was paid to the health impacts of radiation or the safe disposal of **hazardous waste**. Starting in 1951, the research facilities were responsible for storing 2.7 million gallons (10.2 million liters) of concentrated acids and radioactive wastes in open ponds. 76,000 rusting barrels and drums containing mixed radioactive wastes remained on the site. Millions of cubic yards of toxic and **radioactive waste** were also buried in the ground with no containment precautions. 2.4 million pounds (1 million kg) of **mercury** and an unknown amount of **uranium** are estimated to have been released into the ambient **environment** through the air, water and **soil** pathways. The DOE has spent $1.5 billion evaluating the level of contamination and planning **remediation** and treatment activities, and that figure is expected to grow exponentially. Cleanup programs are now the focus of much of the research done by the nuclear scientists at Oak Ridge.

Vegetation and **wildlife** (water fleas, **frogs** and deer) around the laboratories have set off high readings of **radioactivity** in Geiger counters. **Radionuclides** such as strontium, tritium and **plutonium** have been traced in surface waters 40 miles (64 km) downstream of the plant. However, few published studies exist on human health effects from hazardous waste disposal in the area. Studies that examined short term **cancer** rates in the male worker population found no correlation between cancer risk and worker **radiation exposure**; these studies also noted that Oak Ridge employees were actually 20% less likely to die from cancer as the rest of the country—a fact which may be due to the quality of their medical care. Yet studies that followed the health patterns of workers over a period of 40 years documented that cancer risk did indeed increase by 5% with each rem of increasing radiation exposure. These studies also found that white male workers at the laboratories had a 63% higher **leukemia** death rate than the national average.

In 1977 large amounts of employee health records were deliberately destroyed at the Oak Ridge National Laboratories, and the DOE has attempted to influence the interpretation and publication of health studies on the effects of radiation exposure. These facts raise troubling questions for many about the level of knowledge at the research center of the effects of low-level radiation. Both the laboratories and the town itself are considered case studies of the environmen-

tal problems that can be caused by large federal facilities operating under the protection of national security.

Occupational Safety and Health Act (1970)

The Occupational Safety and Health Act (1970) was intended to reduce the incidence of personal injuries, illness, and deaths as a result of employment. It requires employers to provide each of their employees with a workplace that is free from recognized hazards, which may cause death or serious physical harm. The act directed the creation of the **Occupational Safety and Health Administration** (OSHA) within the U. S. Department of Labor. This agency is responsible for developing and promulgating safety and health standards, issuing regulations, conducting inspections, and issuing citations as well as proposing fines for violations. *See also* Right-to-act legislation

Occupational Safety and Health Administration

The Occupational Safety and Health Administration (OSHA) was established pursuant to the **Occupational Safety and Health Act** (1970). Within the Department of Labor, OSHA has the responsibility for occupational safety and health activities pursuant to the Act which covers virtually every employer in the country except all types of mines which are regulated separately under the Mine Safety and Health Act (1977). The Occupational Safety and Health Administration develops and promulgates standards, develops and issues regulations, conducts inspections to insure compliance, and issues citations and proposes penalties. In the case of a disagreement over the results of safety and health inspections performed by OSHA, employers have the right of appeal to the Occupational Safety and Health Review Commission, which works to ensure the timely and fair resolution of these cases.

Ocean Conservatory, The

"The will to understand, conserve, and protect ocean life is at the very core of the Ocean Conservatory's mission. To fulfill this mission, the Ocean Conservatory seeks to: protect marine ecosystems, prevent **marine pollution**, protect endangered marine **species**, manage fisheries for **conservation**, and conserve marine biodiversity." Since its founding in 1972, the Ocean Conservatory (formerly the Center for Marine Conservation) has worked toward these goals. The **endangered species** the group helps to protect include, among many others, **whales**, **dolphins**, seabirds, **seals and sea lions**, and **sea turtles**.

Over 110,000 Ocean Conservatory members nationwide volunteer their time in many different ways, including writing to Congress asking for support of marine conservation, and organizing or participating in beach cleanups across the country. In 1988, for example, more than 16,000 people took part in beach cleanups in Florida and Texas. This number grew and in 2000, 850,000 people cleaned over 20,000 mi (32,187 km) of coast. More than 100 countries have helped the United States in this effort to clean the beaches.

Because of human actions and the ever-changing **environment**, the Ocean Conservatory's goals constantly grow and change. Over the years they have challenged formidable opponents, including Exxon. After the ***Exxon Valdez*** oil spill, the Ocean Conservatory participated in the cleanup and forced Exxon to step up the rescue and rehabilitation of sea otters (*Enhydra lutris*) and other mammals and birds injured by the accident.

Another important Ocean Conservatory activity is the Marine **Habitat** Program. Through this program, the Ocean Conservatory has played a pivotal role in establishing six marine sanctuaries in the United States (there are only eight total), as well as in other countries. One of these, the Silver Back Humpback Whale Sanctuary, protects humpback whales (*Megaptera novaeangliae*) near the Dominican Republic. Established in 1986, it was the world's first whale sanctuary.

Research is an important component of all Ocean Conservatory programs. The group's ongoing research and advocacy has resulted in the adoption of stricter regulations on commercial **whaling** by the International Whaling Commission. The Ocean Conservatory has also helped to pass federal and state regulations requiring the use of turtle ex-

cluder devices (TEDs) on shrimp nets to help protect thousands of endangered sea turtles. Turtles have also benefited from the Ocean Conservatory's research in artificial lighting. The group convinced counties and cities throughout Florida to control the use of artificial light on the state's beaches after proving that it prevents turtles from nesting and lures baby turtles away from their natural habitat.

In 1988 the Ocean Conservatory established a database on marine debris and, subsequently, the group created two Marine Debris Information offices, one in Washington, D.C. and one in San Francisco. These offices provide information on marine debris, especially **plastics**, to scientists, policy makers, teachers, students, and the general public. While many of the Ocean Conservatory's projects are exemplary, one has received so much attention that it has been used as a model by other environmental groups, including the **Environmental Protection Agency** (EPA). The California Marine Debris Action Plan, which went into effect in 1994, is a comprehensive strategy for combating marine debris, and a collaborative effort of the Ocean Conservatory and a wide network of public and private organizations. In 2000 President Clinton enacted the Oceans Act which set up an Oceans Commission to review and revise all policies dealing with the protection of the ocean and the coast. The most recent win for the Ocean Conservatory came in 2001, when Tortugus (200 square nautical miles) was established as the largest no-take marine reserve near Key West, Florida.

Ocean dumping

Ocean dumping is internationally defined as "any deliberate disposal at sea of wastes or other matter from vessels, aircraft, platforms, or other man-made structures at sea, and any deliberate disposal at sea of vessels, aircraft, platforms, or other man-made structures at sea." The **discharge** of sewage and other effluents from a pipeline and the discharge of waste incidental to, or derived from the normal operations of, ships are not considered ocean *dumping*. Wastes have been dumped into the ocean for thousands of years. Fish and fish processing wastes, rubbish, industrial wastes, sewage **sludge**, dredged material, **radioactive waste**, pharmaceutical wastes, drilling fluids, munitions, **coal** wastes, cryolite, ocean **incineration** wastes, and wastes from ocean mining have all been dumped at sea. Ocean dumping has historically been more economically attractive, when compared with other land-based **waste management** options.

The 1972 **Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter**, commonly called the London Convention, came into force in 1975 to control ocean dumping activities. The framework of the London Convention includes a *black list* of materials that may not be dumped at sea under any circumstances (including radioactive and industrial wastes), a *grey list* of materials considered less harmful that may be dumped after a special permit is obtained, and criteria that countries must consider before issuing an ocean dumping permit. These criteria require the consideration of the effects dumping activities can have on marine life, amenities, and other uses of the ocean, and encompass factors related to disposal operations, waste characteristics, attributes of the site, and availability of land-based alternatives. Most ocean dumping permits (90–85%) reported by parties to the London Convention are for dredged material. Currently only three parties to the London Convention dump sewage sludge at sea. Other categories of wastes that are permitted for ocean dumping include inert, geological materials, vessels, and fish wastes. The International Maritime Organization is responsible for administrative activities related to the London Convention, and it facilitates cooperation among the countries party to the Convention. As of 2001, 78 countries had ratified the Convention.

In the early 1990s, the parties to the London Convention began a comprehensive review of the treaty. This resulted in the adoption of the 1996 Protocol to the London Convention. The purpose of the Protocol is similar to that of the Convention, but the Protocol is more restrictive: application of a "precautionary approach" is included as a general obligation; a "reverse list" approach is adopted; incineration of wastes at sea is prohibited; and export of wastes for the purpose of dumping or incineration at sea is prohibited. Under the reverse list approach, dumping is prohibited unless explicitly permitted, and only seven categories of materials may be considered for dumping: dredge material; sewage sludge; fish waste; vessels and platforms; inert, inorganic geological material; organic material of natural origin; and bulky items of unharmful materials when produced at locations with no other disposal options. The Protocol will enter into force after 26 states ratify it (15 of which are party to the London Convention). So far, 16 countries have ratified it (13 of which are party to the London Convention).

Ocean dumping has been used as a method for municipal waste disposal in the United States for about 80 years, and even longer for dredged material. The law to regulate ocean dumping in the United States is the Marine Protection, Research, and Sanctuaries Act of 1972. This Act, also known as the Ocean Dumping Act, banned the disposal of

A ship dumping jarosite waste into the ocean off the Australia coast. (Photograph by Hewetson. Greenpeace. Reproduced by permission.)

radiological, chemical, and biological warfare agents, high-level radioactive waste, and medial waste. It requires a permit for the ocean dumping of any other materials. Such a permit can only be issued where it is determined that the dumping will not unreasonably degrade or endanger human health, welfare, or amenities, or the marine environment, ecological systems, or economic potentialities. Furthermore, all permits require notice and opportunity for public comment. EPA was directed to establish criteria for reviewing and evaluating ocean dumping permit applications that consider the effect of, and need for, the dumping. The Ocean Dumping Act has been revised by the United States Congress in the years since its enactment. In 1974, Congress amended this Act to conform with the London Convention. In 1977, the Act was amended to incorporate a ban by 1982 on ocean dumping of wastes that may unreasonably degrade the marine **environment**. As a result of this ban, approximately 150 permittees dumping sewage sludge and industrial waste stopped ocean dumping of these materials. In 1983, the law was amended to make any dumping of low-level radioactive waste require specific approval by Congress. In 1988, the **Ocean Dumping Ban Act** was passed to prohibit ocean dumping of all sewage sludge and industrial waste by 1992. Virtually all material ocean dumped in the United States today is dredged material. Other materials include fish wastes, human remains, and vessels.

Physical properties of wastes, such as density, and its chemical composition affect the dispersal, and settling of the wastes dumped at sea. Many contaminants such as metals found in trace amounts in natural materials are enriched in wastes. After material is dumped at sea, there is usually initial, rapid dispersion of the waste. For example, some wastes are dumped from a moving vessel, with dilution rates of 1,000 to 100,000 from the ship's wake. As the wake subsides, naturally occurring turbulence and currents further disperse wastes eventually to nondetectable background levels in water in a matter of hours to days, depending on the type of wastes and physical oceanic processes. Dilution is greater if the material is released slower and in smaller amounts, with dispersal rates decreasing over time. Wastes, such as dredged material, that are

much denser than the surrounding seawater sink rapidly. Less dense waste sinks more slowly, depending on the type of waste and physical processes of the dumpsite. As sinking waste particles reach seawater of equal density, they begin to spread horizontally, with individual particles slowly settling to the sea bottom. The accumulation of the waste on the sea floor varies with the location and characteristics of the dumpsite. Quiescent waters with little tidal and wave action in enclosed shallow environments have more waste accumulate on the bottom in the general vicinity of the dumpsite. Wastes dumped in more open, well-mixed ocean waters are transported away from the dumpsite by currents and can disperse over a very large area, as much as several hundred square kilometers.

The physical and chemical properties of wastes change after the material has been dumped into the ocean. As wastes mix with seawater, acid-base neutralization, dissolution or precipitation of waste solids, particle **adsorption** and desorption, volatilization at the sea surface, and changes in the oxidation state may occur. For example, when acid-iron waste is dumped at sea, the buffering capacity of seawater rapidly neutralizes the waste. Hydrous iron oxide precipitates are formed as the iron reacts with seawater and changes from a dissolved to a solid form.

The fraction of the waste that settles to the bottom is further changed as it undergoes geochemical and biological processes. Some of the elements of the waste may be mobilized in organic-rich **sediment**; however, if sulfide ions are present, metals in waste may be immobilized by precipitation of metal sulfides. Organisms living on the sea floor may ingest waste particles, or mix waste deeper in the sediment by burrowing activities. **Microorganisms** decompose **organic waste**, potentially **recycling** elements from the waste before it becomes part of the sea floor sediments. Generally sediment-related processes will act on waste particles over a longer time scale than hydrologic processes in the water column.

The effects of dumping on the ocean are difficult to measure and depend on complex interactions of factors including type, quantity, and physical and chemical properties of the wastes; method and rate of dumping; toxicity to the **biotic community**; and numerous site-specific characteristics, such as water depth, currents (turbulence), water column density structure, and sediment type. Many studies have found that the effects of ocean dumping on the water column are usually temporary and that the ocean floor receives the most impact. Impacts from dumping dredged material are usually limited to the dumpsite. Burial of some benthic organisms (organisms living at or near the sea floor) may occur; however, burrowing organisms may be able to move vertically through the deposited material and fishes typically leave the area. Seagrasses, coral reefs, and oyster beds may never recover after dredged material is dumped on them. There also can be topographic changes to the sea floor. *See also* Dredging

Ocean dumping act

see **Marine Protection, Research and Sanctuaries Act (1972)**

Ocean Dumping Ban Act (1988)

The Ocean Dumping Ban Act of 1988 (Public Law 100-688) marked an end to almost a century of sewage **sludge** and industrial waste dumping into the ocean. The law was enacted amid negative publicity about beach closures from high levels of pathogens and **floatable debris** washing up along New York and New Jersey beaches and strong public sentiment that ending ocean dumping may improve coastal **water quality**. The Ban Act prohibits sewage sludge and industrial wastes from being dumped at sea after December 31, 1991. This law is an amendment to the Marine Protection, Research, and Sanctuaries Act of 1972 (Public Law 92-532), which regulates the dumping of wastes into ocean waters. These laws do not cover wastes that are discharged from outfall pipes such as from **sewage treatment** plants or industrial facilities or that are generated by vessels.

The Ocean Dumping Ban Act was not the first attempt to prohibit dumping of sewage sludge and industrial wastes at sea. An earlier ban was developed by the U. S. **Environmental Protection Agency** (EPA) and later passed by the U.S. Congress (Public Law 95-153) in 1977, amending the 1972 act. This 1977 law prohibits ocean dumping that "may unreasonably degrade the marine environment" by December 31, 1981. Approximately 150 entities dumping sewage sludge and industrial waste sought alternative disposal options. However, New York City, and eight municipalities in New York and New Jersey filed a lawsuit against the EPA objecting to the order to end their ocean dumping practices. A Federal district court granted judgment in their favor, allowing them to continue ocean dumping under a

court order. The court held that the EPA must balance, on a case-by-case basis, all relevant statutory criteria with the economics of ocean dumping against land-based alternatives. After 1981, the New York and New Jersey entities were the only dumpers of sewage sludge, and there were only two companies dumping industrial waste at sea.

In anticipation of the 1988 Ocean Dumping Ban Act, one of the two industries stopped its dumping activities in 1987. The remaining industry, which was dumping hydrochloric **acid** waste, also ceased its activities before the 1988 Ban Act became law. The entities from New Jersey and New York continued to dump a total of approximately eight million wet metric tonnes of sewage sludge (half from New York City) annually into the ocean.

From 1924 to 1987, sludge dumpers used a site approximately 12 miles (19 km) off the coasts of New Jersey and New York. The EPA, working with the **National Oceanic and Atmospheric Administration** (NOAA), determined that ecological impacts such as shellfish bed closures, elevated levels of metals in sediments, and introduction of human pathogens into the marine **environment** were attributed entirely or in part to sludge dumping at the 12 mile site. As a result the EPA decided to phase out the use of this site by December 31, 1987. The sewage sludge dumpers were required to move their activities farther offshore to the 106-mile (171-km) deep water dumpsite, located at the edge of the continental shelf off southern New Jersey. Industries had used this dumpsite from 1961 to 1987.

The Ocean Dumping Ban Act prohibits all dumping of sewage sludge and industrial waste into the ocean, without exception. The law also prohibits any new dumpers, and required existing dumpers to obtain new permits that included plans to phase-out sewage sludge dumping at sea. The Ban Act also established ocean dumping fees and civil fines for any dumpers that continue their activities after the mandated end date. The fines were included in the law in part because legislators assumed that some sludge dumpers would not be able to meet the December 31, 1991 deadline. The law required fees of $100 per dry ton of sewage sludge or industrial waste in 1989, $150 per dry ton in 1990, and $200 per dry ton in 1991. After the 1991 deadline penalties rose to $600 per ton for any sludge dumped, and increased incrementally in each subsequent year. Those ocean dumpers that continue beyond December 31, 1991 are allowed to use a portion of their penalties for developing and implementing alternative sewage sludge management strategies. While the amount of the penalty increased each year after 1991, the amount that could be devoted to developing land-based disposal alternatives decreased.

As part of the law, the EPA, in cooperation with NOAA, is responsible for implementing an **environmental monitoring** plan at the 12 mile site, the 106 mile site, and surrounding areas potentially influenced by dumping activities to determine the effects of dumping on living marine resources. The Ban Act also includes provisions not directly associated with dumping of sewage sludge or industrial waste at sea. Massachusetts Bay-MA, Barataria Terrebonne Estuary Complex-LA, Indian River Lagoon-FL, and Peconic Bay-NY were named as priority areas for consideration to the **National Estuary Program** by EPA. The law also includes a prohibition on the disposal of **medical waste** at sea by public vessels. Finally, the Ban Act requires vessels transporting **solid waste** over the New York Harbor to the Staten Island **Landfill** to use nets to secure the waste to minimize the amount that may spill overboard.

The New Jersey dumpers ceased ocean dumping by March 1991. The two New York counties stopped ocean dumping by December 1991 and New York City, the last entity to dump sewage sludge into the ocean, stopped zn June 1992. Landfilling is currently used as an alternative to ocean dumping and other sewage sludge management strategies are under consideration including **incineration** (after the sludge is dewatered), **composting**, land application, and pelletization. *See also* Convention on the Prevention of Marine Pollution by Dumping of Waste and Other Matter

Ocean farming

Although oceans cover about 70% of the Earth's surface, most food is produced on land areas through agriculture and animal husbandry. This is because 90% of the ocean is unproductive. The productive areas are near shore, such as continental shelfs, **upwellings**, coral reefs, mangrove swamps (also known as mangal communities), and estuaries. The primary reason why these near shore areas are more productive than the open ocean is because of the supply of nutrients which are needed for plant (primarily **phytoplankton**) productivity, which fuels the **food chain/web**.

A worldwide plateau in harvesting of natural fish catch was reached in about 1989, so commercial and sport fisheries

in the oceans cannot be increased unless something is changed. One possibility is to enhance production through fertilization of the water. Another, more practical, possibility is through **aquaculture**. As wild harvests decrease and per capita seafood consumption increases, aquaculture should have an important role. For example, the U.S. imports 60% of its seafood, which contributes to its trade imbalance. Aquaculture can help by providing jobs as well as food products for domestic consumption and for export.

Aquaculture done in seawater is known as **mariculture**. Fish and shellfish are grown in improved conditions to produce more and better food in environments with lower predation and disease. There are several forms of aquaculture: intensive, extensive, and open ocean. In extensive aquaculture, relatively little control is exerted by the mariculturist. These typically occur near shore where organisms are grown in several different ways: floating cages or pens; cordoned-off bodies of water which can be fertilized for enhanced production; or racks and other structures (to grow shellfish). For example, oyster farmers in the **Chesapeake Bay** place clean substrates in selected areas of the bottom mud each summer to collect young oyster larvae (called "spat") as they settle down from the **plankton**. These young oysters attach and grow on the substrates, which are periodically transferred to new locations to prevent them from being covered with mud and **silt**. After several years, the oysters are large enough to be marketed. Other culture methods for bivalves such as oysters and clams utilize the stake method, which involves the use of bamboo or other poles driven into the **sediment** and placed approximately 6 ft (2 m) apart. Nylon ropes hanging from floats can also be used to collect larvae. Following growout, the shellfish are collected and sold on the market. Farmers in the Philippines are able to produce nearly 1.5 tons per acre (0.60 tons per ha) of mussels and 1.7 tons per acre (0.70 tons per ha) of oysters annually. These techniques all have relatively low cost and maintenance. Sometimes there are problems with **pollution** from domestic and industrial waste, and periodic blooms of toxic dinoflagellates (a type of phytoplankton), which create red tides. Red tides can be unhealthy and even lethal to humans.

Intensive mariculture systems involve the production of large quantities of marine animals in relatively small areas. They are relatively expensive to build and maintain, so typically only highly-valued **species** are used, such as lobsters, shrimp, halibut, and certain other fish. Intensive systems can sometimes be located in tanks on land, using either pumped salt water from the nearby ocean or recirculated artificial seawater if the system is located farther away from the ocean. Typically, however, nearshore or offshore floating tanks or pens are used. The organisms are raised from eggs to market size in these controlled environments. **Salmon** have been raised in sea pens (netted cages) for over 20 years along the Pacific coast of the United States and Canada and along the Atlantic coasts of France, Scotland, and the Scandinavian countries, especially Norway. This process typically involves the growth of salmon from fertilized eggs through the fry stage in indoor fresh water hatcheries. This is followed by the transfer of parr (the stage after the fry in which the fish develop vertical lines along their sides) to outdoor tanks or cages in salt water. The fish are fed either commercial pellets or "trash" fish such as herring, capelin, menhaden, and anchovies. The feeding process can be quite labor-intensive, and thus translates into one of the highest expenses for the salmon farmer. After one to two years, the salmon go through a process called smoltification, which involves a physiological change that allows them to live in salt water. The smolt are then transferred to salt water cages for another one to two years until they reach a market size of about 4-12 lb (2-5 kg). Rainbow and sea trouts are handled in a similar way, although they are usually larger when moved into sea pens. As with the extensive method, problems can arise through pollution and red tides.

Most mariculture industries use both nearshore and offshore cages for raising the fish. The nearshore cages are necessary for raising young fish, but the offshore cages are better for raising fish to maturity because of enhanced growing conditions (cleaner water and lower **mortality**). Improvements are still needed, such as methods to remove dead fish, make grading (sorting) of fish possible, make harvesting easier and feeding possible (particularly during adverse weather), and make fouling removal easier. It will also be helpful to construct 24-hour living accommodations on some of the larger offshore units.

A third form of mariculture is known as ocean ranching, or "enhancement aquaculture." This can be compared to cattle ranching on land. For example, salmon are raised in hatcheries until they reach the smolt stage, and are then released at a particular point along the shore where they swim away until they reach reproductive maturity. Like other anadromous fish, they return to that same area several years later, where they are recaptured, processed, and sold on the market. Salmon are ideal fish for this because they are "self-herding." However, normal returns range from only 1-20%, depending upon the **water quality** of the return **environment** and the release size of the fish. For example, Coho salmon fry that were around 0.5 oz (14 g) showed a 1-2% return while those twice this size had a 7-8% return rate. Recent research has shown that released salmon can be imprinted to return to salt water sites, which has the added advantages of lower cost (due to not needing more expensive property located along streams that enter the ocean), and better meat quality (which declines when salmon swim from salt to fresh water). The Sea Run, Inc. salmon company of Kennebunkport, Maine, rears Pacific pink and chum salmon

from eggs to fingerlings in a hatchery located near the **discharge** of an oil-fired power plant. The water has a characteristic temperature and smell which attracts the salmon back to the same area each year. They have also experimented with the release of morpholine and phenyethyl alcohol (synthetic organic compounds) to the water to aid in imprinting.

Similar ocean ranching techniques have been used in other countries. For example, in Japan the natural catch of Red Sea bream has declined for the last 24 years (more than a 51% decrease) due to over-exploitation, so these fish have been raised in tanks and cages since 1962. Other species commonly raised in Japan include salmon, flounder, mackerel, bluefin tuna, shrimp, scallops, and abalone. Many of these species have a high consumer demand and thus are highly priced. Abalone can also be grown to a small size of approximately 1 in (3 cm) and used to re-seed areas where the natural population has declined. They can then be harvested as adults about three to five years later. However, recapture rates are typically low (only 0.5–10%).

Ocean farming or ranching is becoming popular worldwide. In Equador, Mazatlan Yellowtail fish are grown to commercial size (2.7 lb; 1.2 kg) in six months with a 90% survival rate. Other species raised in this country include flounder, snook, red drum, and Pacific pompano. In **Australia**, oysters are commonly raised via sea ranching. Scallops and salmon are now raised in Canada. Mussels, oysters, clams, bream, turbot, and salmon are common mariculture species in Spain, where the warm water allows these species to be grown to market size in a shorter time.

Recent work has been done on algal turf mariculture around some Caribbean islands in natural, unfertilized waters. Test plots have shown that they can raise up to 25 million tons (23 million metric tonnes) of dry algae per year without harming the natural **ecosystem**. This product can then be used for direct human ingestion or as food to raise marine invertebrates (such as West Indian spider crabs, conchs, and whelks) as well as some herbivorous fish. This would be particularly helpful because conch are now an **endangered species** through over-harvesting in this area.

Ocean ranching, along with other forms of aquaculture, is an exciting field that should be in greater demand in the future. Our progeny may depend on it more for global food production to feed the increasing human population.

Ocean outfalls

Pipelines extending into coastal and ocean waters that are used by various industries and municipal **wastewater** treatment facilities to **discharge** treated **effluent**. Some may be simple pipes serving as conveyances from land-based facilities; others include diffusers that help to rapidly dilute effluent or risers that ensure effluent is discharged at a certain height above the ocean floor. The conveyances may extend more than three miles (5 km) offshore, beyond coastal waters into open ocean. Offshore oil and gas exploration, development, and production rigs also possess ocean outfalls. Discharges from these pipes must be permitted under the **Clean Water Act national pollutant discharge elimination system**. *See also* Sewage treatment

Ocean thermal energy conversion

For many years, scientists have been aware of one enormous **reservoir** of energy on the earth's surface: the oceans. As sunlight falls on the oceans, its energy is absorbed by seawater. The oceans are in one sense, therefore, a huge "storage tank" for **solar energy**. The practical problem is finding a way to extract that energy and make it available for human use.

The mechanism suggested for capturing heat stored in the ocean depends on a thermal gradient always present in seawater. Upper levels of the ocean may be as much as 36°F (20°C) warmer than regions 0.6 mile (1 km) deeper. The technology of ocean thermal energy conversion (OTEC) takes advantage of this temperature gradient.

An OTEC plant would consist of a very large floating platform with pipes at least 100 feet (30 m) in diameter reaching to a depth of up to 0.6 mile (1 km). The "working fluid" in such a plant would be ammonia, propane, or some other liquid with a low boiling point.

Warm surface waters would be pumped into upper levels of the plant, causing the working fluid to evaporate. As the fluid evaporates, it will also exert increased pressure. That

The Open Cycle Ocean Thermal Electric Generator requires a water temperature differential of at least 36°F (20° C) to produce both fresh water and electricity. (McGraw-Hill Inc. Reproduced by permission.)

pressure can be used to drive a turbine that, in turn, generates electricity. The electricity could be carried to shore along large cables or used directly on the OTEC plant to desalinize water, electrolyze water, or produce other chemical changes.

In the second stage of operation, cold water from deeper levels of the ocean would be brought to the surface and used to cool the working fluid. Once liquified, the working fluid would be ready for a second turn of the generating cycle.

OTEC plants are attractive alterative energy sources in regions near the equator, where surface temperatures may reach 77°F (25°C) or more. These parts of the ocean are often adjacent to **less developed countries**, where energy needs are growing.

Wherever they are located, OTEC plants have a number of advantages. For one thing, oceans cover nearly 70 percent of the planet's surface so that the raw material OTEC plants need—seawater—is readily available. The original energy source—sunlight—is also plentiful and free. Such plants are also environmentally attractive since they produce no **pollution** and cause no disruption of land resources. Planners suggest that a by-product of OTEC plants might be nutrients brought up from deeper ocean levels and used to feed "farms" of fish or shellfish.

Unfortunately, many disadvantages exist also. The most important is the enormous cost of building and maintaining the mammoth structures needed for an OTEC plant. Also, the temperature differential available under even the best of conditions means that an OTEC plant will not be more than about 3% efficient.

Currently, the disadvantages of OTEC plants are so great that none has even been built. Research continues in a number of countries, but some experts believe that the low efficiency of OTEC means that this technology will never be able to compete economically with other alternative sources of energy. *See also* Desalinization; Energy efficiency; Power plant; Thermal stratification (water)

Octane rating

Octane rating is a method for describing antiknock properties of **gasoline**. Knocking is a pinging sound produced by internal **combustion** engines when fuel ignites prematurely during the engine's compression cycle. Because knocking can damage an engine and rob it of power, gasoline formulations have been developed to minimize the problem. Gasolines containing relatively large amounts of straight-chain **hydrocarbons** (such as n-heptane) have an increased tendency to knock, whereas those containing branched-chain forms (such as isooctane) burn more smoothly. In addition to isooctane, other compounds also reduce engine knocking. By using an index called octane number, it is possible to compare the antiknock properties of gasoline mixtures. A higher octane number indicates that a mixture has the equivalent antiknock properties of a gasoline containing a higher percentage of isooctane.

Although gasoline used as automotive fuel is now "deleaded," gasoline used as aviation fuel still contains **tetraethyl lead** as an octane enhancer and antiknock agent.

Svante Odén

Swedish agricultural scientist

One of the great environmental issues of the 1970s and 1980s was the problem of **acid** precipitation. Research studies suggested that rain, snow, and other forms of precipitation in certain parts of the world had become increasingly acidic over the preceding century. The southern parts of Scandinavia and England, the Northeastern United States, and Eastern Canada were four regions in which the phenomenon was particularly noticeable.

Evidence began to accumulate that the increasing level of acidity might be associated with environmental damage, such as the death of trees and aquatic life. Scientists began to ask how extensive this damage might be and what sources of acid precipitation could be identified.

If any single person could be credited with raising international awareness of this problem, it would probably be the Swedish agricultural scientist Svante Odén. Odén was certainly not the first person to recognize the existence, effects, or origins of acid precipitation. That honor belongs to an English chemist, **Robert Angus Smith**. As early as 1852, Smith hypothesized a connection between **air pollution** in Manchester and the high acidity of rains falling in the area. He first used the term **acid rain** in a book he published in 1872.

Smith's research held relatively little interest to most scientists, however. Those who did study acid rain approached their work with little concern about the **environment** and did so, as one of them later said, "with no environmental consciousness," but simply because "it was an interesting situation."

Odén's attitude was quite different. He had been asked by the Swedish government to prepare a report on his hypothesis that acid rain falling on Swedish land and lakes had its origins hundreds or thousands of miles away. In preparing his report, he came to the conclusion that acid rain might be responsible for widespread **fish kills** then being reported by Swedish fishermen. Odén was shocked by this discovery because, as he later said, it was the "first real indication that acid precipitation had an impact on the biosystem."

Odén's method of dealing with his discoveries was unorthodox. In most cases, a researcher sends the report of his or her work to a scientific journal, which has the report reviewed by other scientists in the same field. If the research is judged to have been well done, the report is published.

In this instance, however, Odén sent his report to a Stockholm newspaper, *Dagens Nyheter*, where it was published on October 24, 1967. Odén's decision undoubtedly disturbed some scientists, but it did have the effect of bringing the issue of acid rain to the attention of the general public.

A year later, Odén published a more formal report of his research, "The **Acidification** of Air and Precipitation, and Its Consequences," in the *Ecology Committee Bulletin*. The article was later translated into English. Odén carried his message about acid precipitation to the United States in person in 1971, when he presented a series of 14 lectures on the topic at various institutions across the country. In his presentations, he argued that acid rain was an international phenomenon that, in Europe, originated especially in England and Germany and was spreading over thousands of miles to other parts of the continent, especially Scandinavia. His work also laid the foundation for Sweden's case study for the **United Nations Conference on the Human Environment** "Air **Pollution** Across National Boundaries" presented at Stockholm in 1972. He further suggested that a

number of environmental effects, such as the death of trees and fish and damage to buildings, could be traced to acid precipitation. Odén's passionate commitment to publicizing his findings about acid precipitation was certainly a critical factor in awakening the world's awareness to the potential problems of this environmental danger.

Odor control

Refuse-handlers and many industries release unpleasant odors into the air which can travel for miles. Odors inside factories can also make it difficult for people to work, and pollutants can impart a strong odor to water.

Odors can be released from **chemicals**, chemical reactions, fires, or rotting material. The air carries odor-producing gas molecules, and they are detected by breathing or sniffing. The molecules stimulate receptor cells in the nose, which in turn send nerve impulses to the brain where they are processed into information about the odor.

Research is being performed to quantify and characterize odors. Tests such as sniff **chromatography**, **emission** rate measurement, and hedonics are being used in an effort to develop a better definition of what offensive odors are.

Scientists have found that the perception of odors is highly subjective. What one person might not like, another person might not be able to smell at all, and what people define as an offensive odor depends on age and sex, as well as other characteristics.

One method of controlling unpleasant smells is deodorizers. Deodorizers either disguise offensive odors with an agreeable smell or destroy them. Some deodorizers do this by chemically changing odor-producing particles while others merely remove them from the air. Disinfectants, such as formaldehyde, can kill bacteria, **fungi** or molds that create odors. Odors can also be removed through ventilation systems. The air can be "scrubbed" by forcing it through liquid or through **filters** containing such materials as charcoal, methods which trap and remove odor-producing particles from the air. Factories can also employ a process known as "re-odorization," which works on the principle that there are seven basic odor types: camphoraceous, mint, floral, musky, ethereal, putrid, and pungent. The process is based on the theory that different combinations of these odor types produce different smells, and re-odorization releases chemicals into the air to combine with the regular factory odors and generate a more pleasant smell.

Aeration is one method of removing objectionable odors from water. The surface of the water is mixed with air and the oxygen oxidizes various materials that would otherwise turn the water foul. Aeration can be accomplished by running the water over steps or spraying the water through nozzles. Trickling the water over trays of coke also helps eliminate offensive odors, and adding activated charcoal can have the same effect.

Even though science has shown that the perception of odors is subjective, many people are offended by them. It is often considered a quality-of-life issue, and politicians have been strongly influenced by their constituencies. Nuisance regulations have been passed in many states and municipalities, and though they often vary, their attempts to distinguish between acceptable and unacceptable odors are often vague and difficult to apply. Proving that odors interfere with the quality of life is not only subjective but nearly impossible. Refuse-handlers and factories are perhaps the most adversely affected; they often receive heavy fines for odors, although there is no proven method for eliminating them. Many believe a more concrete system of regulations is needed, but science has not been able to provide the basis on which to build one. *See also* Noise pollution; Pollution control

Dr. Eugene P. Odum (1913 –)

American ecologist

Eugene P. Odum has been called "the ecologist's ecologist," meaning that he has been of special significance to his colleagues in the development of the discipline, and in formulat-

ing its content, outlines, and boundaries. He helped lay the foundations for what might be called the "modern" study of **ecology** in the 1940s and 1950s by redirecting the field to studies based on energetics, on the relatively new **ecosystem** concept, and on functional as well as structural analyses of living communities. From early in his career, he has worked to define general principles in ecology. His colleagues and associates have recognized him by electing him president of the **Ecological Society of America**, through election to the **National Academy of Sciences**, and through the awarding of prestigious prizes, including the Tyler Award in 1977 and the Crafoord Prize in 1987.

Odum was born in Lake Sunapee, New Hampshire, to an academic family. His father, Howard W. Odum, was a well-known sociologist, remembered today especially for his work on regionalism. His brother, Howard T. Odum, is a well-known systems ecologist. Eugene Odum received his bachelor's and master's degrees in biology from the University of North Carolina, and his Ph.D. in ecology and ornithology from the University of Illinois in 1939. He spent brief stints as an instructor at Western Reserve University and as a research biologist at the Edmund Niles Huck Preserve in New York. In 1940, he accepted a teaching position at the University of Georgia, spent the next four decades there, and since his retirement in 1984, has been an emeritus professor. During his tenure in Georgia, the university has become a world center for the study of ecology, through various departments but also through the Institute of Ecology, which he helped initiate and of which he was the longtime director.

Odum's best-known work is his "landmark" general text, *Fundamentals of Ecology*, first published in 1953, with a third edition published in 1971. This text dominated the market for two decades and is still a book to consult, including an extensive and still useful reference list. Odum revised the third edition "in light of the increasing importance of the subject in human affairs." That edition is organized into three parts: basic ecological principles and concepts, emphasizing energy and ecosystems; "the **habitat** approach," which discusses freshwater, marine, estuarine, and terrestrial ecology; and applications and technology, which includes chapters on resources, **pollution** and **environmental health**, radiation ecology, remote sensing, and microbial ecology. Since Odum is a well-known radiation ecologist, that chapter especially is still timely.

Odum's early work was on birds, an interest threaded into his publications for many years. His research focused for several years on various aspects of radiation ecology. He turned early to an emphasis on energetics and on ecosystem studies, becoming almost as well known for systems ecology as his younger brother. A lot of his work has been on productivity in estuaries and marshes. And he is known for his work on old fields in the southern United States. That research has, in many instances, been applied to problems in environmental management, and to issues of human impact and reciprocity.

In recent years, a considerable amount of his energy has been devoted to human interactions with and impacts on environmental systems. That last interest has turned Odum into something of a philosopher, resulting in the publication of several papers on values and ethics. One influence of his thinking that will be debated for a long time is his repeated attempts to outline ecology as an integrative discipline, and to locate ecologists as scientists interested in every level of integration, from micro to macro. That work has led him several times, with mixed success, to move away from the classical reductionist approach in science and to try an outline for a **holistic approach** in ecology.

Office of Civilian Radioactive Waste Management

Humans have been using nuclear materials for nearly 50 years. Nuclear reactors and **nuclear weapons** account for the largest volume of these materials, while industrial, medical, and research applications account for smaller volumes. One of the largest single problems involved with the use of nuclear materials is the volume of wastes resulting from these applications. By one estimate, 8,000–9,000 metric tons (8,816–9,918 tons) of high-level radioactive wastes alone are produced in the United States every year. It is something of a surprise, therefore, to learn that as late as 1982, the United States had no plan for disposing of the radioactive wastes produced by its commercial, industrial, research, and defense operations.

In that year, the United States Congress passed the Nuclear Waste Policy Act establishing national policy for the disposal of **radioactive waste**. Responsibility for the implementation of this policy was assigned to the **U.S. Department of Energy** through the Office of Civilian **Radio-**

active Waste Management (OCRWM). OCRWM manages federal programs for recommending, constructing, and operating repositories for the disposal of high-level radioactive wastes and spent nuclear fuel. It is also responsible for arranging for the interim storage of spent nuclear fuel and for research, development, and demonstration of techniques for the disposal of **high-level radioactive waste** and spent nuclear fuel.

In addition, OCRWM oversees the Nuclear Waste Fund, also established by the 1982 act. The fund was established to enable the federal government to recover all costs of developing a disposal system and of disposing of high-level waste and spent nuclear fuel. It is paid for by companies that produce **nuclear power**, power consumers, and those involved in the use of nuclear materials for defense purposes.

OCRWM has published a number of short pamphlets dealing with the problem of waste disposal. They cover topics such as "Nuclear Waste Disposal," "What Will a Nuclear Waste Repository Look Like?" "What Is Spent Nuclear Fuel?" "Can Nuclear Waste Be Transported Safely?" and "How Much High-Level Nuclear Waste Is There?"

OCRWM experienced a number of setbacks in the first decade of its existence. No state was willing to allow the construction of a high-level nuclear waste repository within its borders. The technology for immobilizing wastes seemed still too primitive to guarantee that wastes would not escape in to the **environment**.

Eventually, however, OCRWM announced that it had chosen a site under **Yucca Mountain** in southeastern Nevada. The site lies on the boundaries of the **Nevada Test Site** and Nellis Air Force Base. It is near the town of Beatty, 100 mi (161 km) northwest of Las Vegas. The site has been studied since 1977 and should be ready to receive wastes early sometime around 2010. Some residents of Nevada are unhappy with the choice of Yucca Mountain as a nuclear waste repository, however, and continue to fight OCRWM's decision.

Office of Management and Budget

The Office of Management and Budget (OMB), established in 1939 within the office of the President, determines both how much money will be spent by the federal government and what kinds of regulations will be adopted to implement all environmental and other legislated programs.

According to the 1946 Administrative Procedures Act, regulations "interpret, implement or prescribe law or policy." Draft regulations must be publicized, and agencies must incorporate public comments into the final regulations. Executive Orders 12291 and 12498, issued in 1981 and 1984, respectively, gave the Office of Information and Regulatory Affairs (OIRA), a division of OMB, the authority to review and approve all regulations and paperwork drafted by the **Environmental Protection Agency**, as well as all other federal agencies.

Office of Surface Mining

In 1977 the Office of Surface Mining(OSM) was created to police **coal** extraction within the United States and to enforce the federal **Surface Mining Control and Reclamation Act** (SMRCA). Under the auspices of OSM, citizens are empowered to enforce **reclamation** of surface mines, as well as deep mines, that have damaged surface features.

The government, industry, or a combination of both is required to pay all expenses, including legal fees, when citizens bring successful administrative or judicial complaints for noncompliance under the SMRCA. The reclamation of abandoned mines is funded by a tax on coal. To fund the reclamation of new mines OSC requires performance bonds that must cover the cost of reclamation should the operator not complete the process.

The majority of mining states have been granted "primacy" by OSM, which means that the individual states are authorized to handle reclamation enforcement, with OSM stepping in only when states fail to enforce the SMRCA. There are almost 30,000 known violations that remain uncorrected, yet OSM issues less than 25 citations a year. The

majority of citations issued are disposed of by vacating the citation or by making arrangements with the company.

There are 24,000 operations including surface mines, deep mines, refuse piles and prep plants that come under the act, (including those that went into operation after 1977); about 17,000 of these have been reclaimed. Many of these reclaimed sites are merely grass planted over **desert**, incapable of supporting any form of **wildlife**. The reclamation plans developed for many **surface mining** sites designate the post mining **land use** to be pastureland, but due to the remoteness and inaccessibility, many reclaimed sites sit idle devoid of all wildlife.

Environmentalists and other opponents of the mining industry charge that coal industries and OSM personnel are the same group. It is interesting to note that Harry Snyder, the current director of OSM, was a former lobbyist for CSX railroad and is a heavy investor in coal. According to many critics the coal industry has become adept at manipulating the OSM and SMCRA for its own purposes. The OSM is currently trying to push through legislation that would eliminate the SMRCA's attorney fee provisions. The agency is also in the process of throwing out numerous other SMCRA regulations that are burdensome to the coal industry, including one that bans deep mining from national parks and wildlife refuges.

Off-road vehicles

Off-road vehicles (ORVs) include motorcycles, dirt bikes, snowmobiles, bicycles, and all-terrain vehicles (ATVs) that can be ridden or driven in areas where there are no paved roads. While the use of off-road vehicles has gained in popularity, conservationists and landowners have prompted some legislatures to restrict their use because of the damage the vehicles do to the **environment**.

During eight years under President Bill Clinton (1946–), environmentalists continued their progress in limiting or banning the use of off-road vehicles in federally protected areas, such as national parks and forests. However, with the election of George W. Bush (1946–) in 2000, environmentalists began to worry their progress might be in jeopardy. As of 2002, the Bush administration had sent mixed signs regarding off-road vehicle use on **public land**.

In October 2001, the U.S. **Environmental Protection Agency** (EPA) announced plans to impose **pollution control** restrictions on off-road vehicle engines. The EPA said off-road vehicles, including snowmobiles, account for 13 percent of hydrocarbon **emission** released into the **atmosphere** each year. The EPA wants off-road vehicle manufacturers to switch from two-cycle to four-cycle engines starting in 2006. Snowmobiles would be required to reduce emissions by 30% in 2006 and 50% in 2010. The Clinton administration had planned to phase-out snowmobiles altogether in **Yellowstone National Park**.

In 2002, the federal **Bureau of Land Management** (BLM) proposed lifting the ban on off-road vehicles in the 50,000-acre Imperial Sand **Dunes Recreation** Area in California. However, that same year, the BLM closed nearly 18,000 acres of federal land in the California's Mojave **Desert** to off-road vehicles. The closing was necessary to protect the **desert tortoise**, a threatened **species**.

A popular sport in desert areas, mountain passes, and riverbeds, owners and drivers of off-road vehicles defend their right to ride wherever they like. They contend that the Clinton administration policy of closing federal land to ORVs was discriminatory, since it favored recreational use of public land only for certain groups of the public, such as hikers, campers, and backpackers. But environmentalists claim that the vehicles scar the land, kill **wildlife**, destroy vegetation, and cause noise, safety and **pollution** problems. The knobby tires of mountain bicycles contribute to **erosion** in delicate desert areas and along the sides of steep mountain trails. Motorized off-road vehicles are more devastating to local **ecology** as landowners across the country are finding.

In Missouri's Black River, off-roaders typically discard beer cans, used baby diapers, and empty motor-oil cans. Usually clear, the Black River in places runs as green as a sewage ditch when algae are stirred up by the commotion of off-road vehicles. Some drivers drain their crankcases into the river. Inevitably, the oil and gas from motorized vehicles seeps into the river **ecosystem**. A bill passed by the Missouri legislature in April 1988 restricted the vehicles to areas of

A rider maneuvers his Honda three-wheeler over sand dunes. (Photograph by Inga Spence. Tom Stack & Associates. Reproduced by permission.)

the river where landowners gave permission. Since much of the area is not posted, however, the law failed to halt a good deal of the use of off-road vehicles in the river.

At the Chincoteague **Wildlife Refuge** in Virginia, an environmental assessment of the effects of off-road vehicles and foot traffic found the effects devastating to some species, particularly the threatened piping plover. The assessment recommended that the area be closed to the vehicles and to all recreation during the nesting season, concluding that the nesting site is subject to damage not only from off-road vehicles, but also from the human intrusion accompanying the use of these vehicles.

In California, about 500,000 acres of public land are open to use by off-road vehicles, and California conservationists have fought since the late 1980s to ban the sport in state parks. Off-roaders, however, waged their own battle. Editorials in magazines for off-road vehicles users urged readers to ignore posted property, sue for the right to use the land, and lobby their state and federal elected officials.

More than 30 states now have enacted legislation that regulates the sale and use of off-road vehicles, especially motorized ones. The legislation was more a reaction to the safety problems inherent in three-wheel vehicles than to the detrimental ecological effects of the vehicles in pristine areas. The Consumer Product Safety Commission listed almost 1,000 deaths related to the use of ATVs from 1982 to 1988, and hundreds of product liability suits have been brought against manufacturers.

Offshore drilling

see **Oil drilling**

Ogallala Aquifer

The Ogallala **Aquifer** is an extensive underground **reservoir** that supplies water to most of the irrigated agriculture in the central United States. Discovered early in the nineteenth century, this aquifer—also known as the High Plains regional aquifer—became a major economic resource in the 1960s and 1970s when advanced pumping technology made large-scale **irrigation** possible. In 1980 this aquifer supported 170,000 **wells** and provided one third of all irrigation water pumped in the United States. In the last several decades, Ogallala-irrigated agriculture has redefined the landscape of the central United States by fostering economic expansion, **population growth**, and the development of large-scale agribusiness in an **arid** region.

The High Plains regional aquifer underlies eight states, including most of Nebraska and portions of South Dakota, Wyoming, Colorado, Kansas, Oklahoma, Texas, and New Mexico. Covering an area of 175,000 square miles (453,250 sq km), the aquifer runs 800 miles (1,288 km) from north to south, and stretches 200 miles (322 km) at its widest point. Nebraska holds by far the greatest amount of water, with 400–1,200 feet (130–400 m) of saturated thickness, while much of the aquifer's southern extent averages less than 100 feet (30 m) thick. Geologically, this aquifer comprises a number of porous, unconsolidated sand, **silt**, and clay formations that were deposited by wind and water from the Rocky Mountains. The most important of these formations is the

The Ogallala, or High Plains, Aquifer. (Line drawing by Laura Gritt Lawson. U. S. Geological Survey Water Resource Investigations Report.)

Ogallala formation, which makes up seventy-seven percent of the regional aquifer. The aquifer's total drainable water is about 3.25 billion acre feet.

Large volume use of **groundwater** became possible with the invention of powerful pumps and center-pivot irrigation in the late 1950s. The center pivot sprays water from a rotating arm long enough to water a quarter section (160-acre) field. This irrigation technique is responsible for the characteristic circular pattern visible from the air in most agricultural landscapes in the western United States. Although installation is extremely expensive, center pivots and powerful pumps enable farmers to produce great amounts of corn, wheat, sorghum, and cotton where low rainfall had once made most agriculture impossible.

High-volume pumping has also reduced the amount of available groundwater. Most water in the High Plains aquifer is "fossil water," which has been stored underground for thousands or millions of years. New water enters the aquifer extremely slowly. In most of the Ogallala region, pumping exceeds recharge rates, a process known as water mining, and the net volume is steadily decreasing. Region-wide, less than 0.5% of the water pumped each year is replaced by **infiltration** of rainwater. At current rates of pumping, the resource should be 80% depleted by about 2020.

As saturation levels in the aquifer fall, consequences on the surface are clearly visible. Many streams and rivers, dependent on groundwater for base flow, run dry. The state of Kansas alone has lost more than 700 miles (1,126 km) of rivers that once flowed year round. Center pivot irrigation, requiring a well that can pump 750 gallons (2,839 liters) per minute, is beginning to disappear in Texas and New Mexico, where the aquifer can no longer provide this volume. **Groundwater pollution** is becoming more concentrated as more **agricultural chemicals** seep into a shrinking reservoir of Ogallala water. Many high plains towns, formerly rich with pure, clean groundwater, now have tap water that is considered unhealthy for children and pregnant women. As the Ogallala runs dry, the region's demographics are also changing. Many farmers assumed heavy debt burdens in the 1970s when they installed center pivots. Drying wells and falling production have led to farm foreclosures and the depopulation of small, rural towns. Regional populations that swelled with irrigated agriculture are beginning to shrink again. Land ownership, formerly held by independent families and ranchers, is increasingly in the hands of banks, insurance companies, and corporations, which provide little support to local communities.

Oil

see **Petroleum**

Oil drilling

Petroleum occurs naturally in the earth in porous rock, found anywhere from thousands of meters underground all the way to the earth's surface. The porous layer of rock normally lies between two nonporous layers, so oil does not flow out of its **reservoir**. In most cases water and/or **natural gas** occur along with petroleum in the rock. Oil can be extracted from the rock by sinking a pipe into the earth until it penetrates the saturated porous rock. In most cases, oil will then begin to flow of its own accord out of the rock and into the pipe.

The upward flow of oil can be caused by a number of different factors. In some cases, the porous layer of rock is covered by a hollow cap filled with natural gas. Pressure of the gas forces petroleum out of the rock into the pipe. In some cases, gas pressure will be so great as to force oil out of a new well in a fountain-like effect known as a "gusher."

In other cases, the pressure of water also present in the saturated rock pushes oil towards and into the pipe. In still other instances, gases dissolved in petroleum exert pressure on it, forcing it up the pipe.

The ease with which oil flows through a rock layer and into a well depends on a number of factors. In addition to water and gas pressure, viscosity of the oil determines how easily it will move through rock. Even under the most favorable conditions, no more than about 30 percent of the oil in a rock layer can be extracted by any of the natural methods described above.

The term *primary recovery* is used to describe the natural flow of oil by any of the means described above. By adding a pump to the well—*secondary recovery*—an additional quantity of oil can be removed. Even after primary and secondary recovery, however, 40–80% of the oil may still remain in a reservoir. All or most of that oil can be recovered by a variety of techniques described as *tertiary recovery*.

All forms of tertiary recovery involve the injection of some kind of fluid into the oil-bearing stratum. A long pipe is stuck into the ground parallel to the oil-recovery pipe. Into the second pipe is injected a mixture of **carbon dioxide** in water, steam, or some combination of water and **chemicals**. In any one of these cases, the injected material diffuses through the oil-bearing rock, pushing the petroleum out and up into the recovery pipe.

Yet another tertiary recovery approach is to set fire to the oil remaining in one part of the stratum. The heat thus generated reduces the viscosity of the unburned oil remaining in the stratum, allowing it to flow more easily into the recovery pipe. Any form of tertiary recovery is relatively expensive and is not used, therefore, until the price of oil justifies this approach. The same can be said for off-shore drilling.

Organic materials washed into the oceans from rivers often settle on the sloping underwater area known as the continental shelf. In this oxygen-free **environment**, those materials often decay to produce petroleum and natural gas. In recent decades, oil companies have found it profitable to locate and drill for oil in these off-shore reserves.

The technique for drilling from off-shore **wells** is generally the same as that used on land. The major difference is that before drilling may begin a stable platform on the water's surface for the drilling rig and ancillary equipment must be constructed. The drilling platform must be protected from high winds, waves, and serious storms. In addition, special safeguards must be taken to protect pipes from breaking and releasing oil into the environment. *See also* Oil Pollution Act (1990); Oil spills

Oil embargo

The year of 1973 marks one of the most important turning points in the history of the twentieth century. Prior to 1973, the world had become accustomed to a plentiful supply of inexpensive **fossil fuels**: **coal**, **petroleum**, and **natural gas**. Developed nations had built economies that depended not just on these fossil fuels, but also on their relatively low cost. Patterns of urban growth in the United States, to take just one example, reflected the fact that the average person could easily afford to drive her **automobile** many miles a day. The average price of a barrel of oil in 1973, for example, was $2.70 and the average cost of **gasoline** at the pump about 35¢ a gallon.

A number of factors combined in 1973, however, to change this picture dramatically. The most obvious of those factors was a decision made by the Arab members of the **Organization of Petroleum Exporting Countries** (OPEC) to cut back on its export of petroleum to many nations of the world. The reason given for this decision was the support given by the United States to Israel during the 18-day war with Syria and Egypt. The action, taken on October 18, 1973, reduced the direct flow of oil from the Arab states to the United States to zero.

OPEC had been established in 1960 by a Venezuelan oil man Juan Perez Alfonso. An extremely conservative businessman who rode a bicycle and read by candlelight to save

Cars line up for gasoline along Route 4 in Fort Lee, New Jersey, in 1974. (AP/Wide World Photos. Reproduced by permission.)

energy, Perez Alfonso saw OPEC as an organization that could encourage **energy conservation** throughout the world.

His objectives were certainly achieved in some places as a result of the 1973 embargo. Americans, along with citizens of other developed nations, found themselves waiting in long lines to buy gasoline, turning their thermostats down to 60°, and learning how to live with less energy in general.

The embargo also had a devastating effect on national economies. In the United States, inflation climbed to more than 10 percent a year, an enormous trade deficit developed, and interest rates climbed to the high teens. Elsewhere, a global recession began.

By the time the embargo ended in March 1974, oil prices had climbed to nearly $12 a barrel, an increase of 330 percent. Gasoline prices had also begun to climb, reaching 57% a gallon by 1975, 86¢ a gallon by 1979, and $1.19 a gallon by 1980.

The embargo caused developed nations to rethink their dependence on fossil fuels. Research on **alternative energy sources** such as wind, tides, geothermal, and **solar energy** suddenly attained a new importance. The United States government responded to the new era of expensive energy by formulating an entirely new **energy policy** expressed in such legislation as the Energy Policy and **Conservation** Act of 1976, the Energy Conservation and Production Act of 1976, the **Energy Reorganization Act** of 1974, and the National Energy Act of 1978.

Interestingly enough, the OPEC embargo had impacts that were relatively little known and discussed at the time. For example, the United States was importing only about 7 percent of its oil from Arab nations in 1973. Yet, almost as soon as the embargo was announced, prices at the gasoline pump began to rise. Such a fast response is, at first, difficult to understand since "old," cheap oil was still on its way from the Middle East and was still being processed, shipped and stored by petroleum companies.

The embargo must also be understood, therefore, as an opportunity for which oil companies had been looking to increase their prices and profits. In the years preceding the embargo, these companies had been feeling increased pressures from domestic environmental groups to cut back on drilling in sensitive areas. They were also losing business to small, independent competitors.

The embargo afforded the companies an opportunity to turn this situation around and once more increase profitability, which they did. In the one year following the embargo, for example, the seven largest oil companies reported profits from 40–85%. Two years after the embargo, one of these companies (Exxon) became the nation's richest corporation, with revenues of $45.1 billion.

Neither have the long term effects of the embargo been what observers in 1973 might have expected. In 1990 the United States imports a larger percentage of its oil from Arab OPEC members than it did in 1973. And the enthusiasm for alternative energy sources of the 1970s has largely

diminished. *See also* Alternative fuels; Energy conservation; Geothermal energy; Wave power; Wind energy

Oil shale

The term oil shale is technically incorrect in that the rock to which it refers, marlstone, is neither oil nor shale. Instead, it is a material that contains an organic substance known as *kerogene*. When heated to a temperature of 900°F (480°C) or more, kerogene decomposes, forming a petroleum-like liquid and a combustible gas. Huge amounts of high-grade oil shale exist in the western United States. By some estimates, these reserves could meet the nation's fuel needs for about a century. Although the technology for tapping these reserves already exists, it is still too expensive to compete with conventional **fossil fuels** or other sources of energy now in use. *See also* Alternative fuels

Oil spills

An oil spill is the common expression used to refer to the release of crude oil or **petroleum** into water or on land. Crude oil released in this way represents an evironmental issue of great concern because spills threaten animals, plant life and other marine resources. Oil can also cause long term environmental and economic damage to the marine **ecosystem** near a spill. According to a 2002 report from the **National Academy of Sciences**, approximately 210 million gal (790 million l) of oil spills into the oceans each year. Sources include the **wells** from which oil is extracted and the ships used to transport it, as well as natural oil **seepage** from geologic formations below the seafloor, as for example in **Coal** Oil Point along the California Coast, where an estimated 2,000–3,000 gal (7,570–11,350 l) of crude oil is released naturally from the ocean floor every day. While accidental tanker oil spills receive the most publicity, they only account for approximately 20% of the crude oil released into the oceans each year by human activity with the remainder largely due to routine oil tanker ship maintenance operations such as **loading**, discharging, and emptying ballast tanks.

Oil and spills are often measured in gal (l) or "barrels of petroleum"; a barrel equals 42 gal (159 l), and a (metric) tonne equals 7.2 barrels. Tankers sometimes transport more than 30,000 barrels of oil (200,000 tonnes).

According to a 2002 study performed by the **National Research Council**, a total of 29 million gal (110 million l) of petroleum are released into North American ocean waters each year as a result of human activities or carelessness. However, only a small fraction of that environmental **pollution** is due to pipeline ruptures or oil tanker spills. Approximately 85% of those spills involve land-based runoffs from cars and trucks, fuel dumping by commercial airplane pilots, and emissions from small boats and crafts.

Oil and its properties

The word oil usually refers to petroleum, a liquid that occurs in **nature** and consists of **hydrocarbons**, a group of organic chemical compounds of **hydrogen** and **carbon** atoms. Petroleum, also known as crude oil, is classified in categories that range from light, volatile oils (Class A) to heavy, sticky oils (Class C), depending on physical properties and charcateristics. Refined oil is crude oil that has been processed for use as **gasoline**, kerosene, lubricating oil, and fuel oils of varying weights.

In spills, the majority of oils spread horizontally to form a smooth, slippery layer on the surface of water. This surface is called a slick. When oil stays on the ocean surface, it cuts off the oxygen supply to the marine life below. The oil also kills birds, animals, and can harm the water supply and the coastline.

"Fate" is the term used by scientists to describe what happens to the various oil components after a spill. Factors that determine fate include the type of oil, the quantity spilled, water temperature, and **climate**. The fates of oil are natural processes. **Weathering** is a series of chemical and physical changes that causes oil to break down and become heavier than water. Evaporation occurs when lighter substances in the oil evaporate and leave the water surface.

About half of a spill may evaporate within several days. Warm water temperatures help this process. Although oil evaporates, the process of emulsification may increase the size of a spill. Emulsions are a mixture of small drops of oil and water. Wave action mixes together a water-in-oil mixture called "chocolate mousse." Mousse may remain in the **environment** for months or years, according to the United States **Environmental Protection Agency** (EPA).

Oxidation reactions may also result from the contact of oil with water and oxygen. Portions of the slick cling together in tar balls. Biodegradation occurs when micro-

organisms like bacteria feed on oil. How oil affects the environment depends on the rate at which the oil spreads. The slick is affected by surface tension, which is the measure of the attraction between the surface molecules of a liquid. Oil with a higher surface tension usually remains in one place. If the surface tension is lower, the oil tends to spread. Wind and water currents also cause oil to spread. Furthermore, higher temperatures can reduce surface tension so oil tends to spread more in warmer water.

Light refined products like gasoline and kerosene spread on the water surface and quickly penetrate porous **soil**. The risk of fire and toxic hazards is high, but these oils evaporate quickly and leave little residue. Heavier refined oil products are less of a fire and toxic hazard risk.

Oil spills and their aftermaths

After a spill, oil can spread very quickly unless contained, for example, by a boom or a boat slip. The lighter the oil, the faster it spreads out. For example, gasoline spreads faster than heavy fuel oil. Faster currents and winds can also cause oil to spread faster and temperature can sometimes make a difference as well because colder oil does not flow as well and spreads more slowly.

Oil spills have occured all over the world. The Cutter Information Corporation tracks oil spills involving at least 10,000 gal (34 tonnes). It reports that spills of that magnitude have occurred in the waters of 112 countries since 1960. Oil spills are also known to happen more often in some parts of the world. Major oil spills from tankers have occurred in the Gulf of Mexico (267 spills); the northeastern United States (140 spills); the **Mediterranean Sea** (127 spills); the Persian Gulf (108 spills); the North Sea (75 spills); Japan (60 spills); the Baltic Sea (52 spills); the United Kingdom and English Channel (49 spills); Malaysia and Singapore (39 spills); the west coast of France and north and west coasts of Spain (33 spills); and Korea (32 spills).

The aftermath of an oil spill always results in environmental damage. During the 1991 Gulf War, oil was spilled onto Kuwaiti land and into the Arabian Gulf when the Iraqi Army began destroying tankers, oil terminals, and oil wells. Approximately 9,000,000 barrels of oil were spilled in the Arabian Gulf, forming a slick measuring some 600 mi^2 (1,600 km^2). When the slick moved close to Saudi Arabia, people pumped water into the area between the beach and the oil. Some 400 mi (640 km) of the western shores of the gulf was oiled, with Saudi Arabian shores the most severely affected, the spill destroying most of its shrimp fields.

In 1989, the ***Exxon Valdez*** ran aground Bligh Reef in **Prince William Sound**, Alaska, spilling more than 11 million gal (41 million l) of crude oil. The spill was the largest in United States history and focused worldwide attention to the damage caused by oil spills. The first day, thousands of animals died. During the month after the spill, more than 7,000 sea otters in Prince William Sound died. Other casualties included more than 100 bald eagles, and 36,000 birds including puffin, auklet and other species. As the oil spread, people tried to rescue wildlife. They had to calm terrified animals. Rescuers fed animals and kept them warm. When the animals were stronger, people started cleaning birds and mammals.

Three methods were used in the effort to clean up the spill, namely burning, mechanical cleanup and the use of chemical dispersants. Burning was conducted during the early stages by placing a fire-resistant boom on tow lines, with two ends of the boom each attached to a different ship. The two ships with the boom between them sailed very slowly throughout the slick until the boom was full of oil. They then towed the boom away from the slick and the oil was set on fire. The procedure did not endanger the main slick nor the *Exxon Valdez*, because a safe distance separated them. Mechanical cleanup was also carried out using booms and skimmers with people cleaning birds and mammals. Chemical dispersants were also used in the cleanup effort but were not very effective because there was not enough wave action to mix the dispersant with the oil in the water.

The aftermath of the *Exxon Valdez* spill included the adoption of the federal Oil Pollution Act of 1990. The law created a spill clean-up fund, set penalties for oil spillers, and directed the federal government to respond quickly to oil spills. In 1993, federal law required a double hull for all tankers carrying oil to the United States.

The United States produces an average of 125 billion gal (473 billion l) of crude oil each year. The country imports an additional 114 billion gal (430 billion l) and 29 million gal (110 million l) of oil enter coastal waters off the United States each year. Nearly 85% of that oil comes from polluted rivers, small boats, vehicles, and street run-off. As a result, the National Academy of Sciences has called on the federal government to work with state environmental agencies to address these issues.

In the United States, various techniques are used to respond to oil spills. Containment and recovery are usually the primary goals of the response team. Equipment includes booms and skimmers that are used to collect the oil and store it. Floating booms are mechanical barriers that extend above and below the surface of the water to stop the spread of oil. They can be used to surround a slick completely and reduce its spread, to protect harbor entrances or biologically sensitive areas, and to divert oil to an area where it can be recovered. Dispersants are **chemicals** used to break up oil and keep it from reaching the land. Furthermore, the spill response team works to keep birds and animals away from the oil spill area. Their equipment includes propane scare cans, floating dummies, and helium balloons.

Workers clean up an oil-fouled California beach. (Corbis-Bettmann. Reproduced by permission.)

Oil spills on a global level

The EPA, the **National Oceanic and Atmospheric Administration**, and the American Petroleum Institute are among the sponsors of the International Oil Spill Conference. Since 1969, the conference has been scheduled every two years. Goals include delineating the overall oil spill problem and exploring ways to prevent and respond to spills. A 2003 conference was planned in Vancouver, British Columbia.

Oil spills are a global problem. In 1999, the tanker *Erika* caused the greatest oil spill in European history. The tanker broke and spilled 3 million gal (11 million l) of oil off the coast of Brittany, France. The following year, a pipeline ruptured and spilled 343,200 gal (1.3 million l) of oil into Guanabara Bay in Brazil. And in 2000, the tanker *Westchester* ran aground south of New Orleans, spilling 567,000 gal (2.1 million l) of oil into the Mississippi River. That was the largest spill in the United States since the *Exxon Valdez*.

Environmental organizations concerned with oil spills include the Sea Shepherd Conservation. Founder Paul Watson's goal in 2002 was to create a coalition of oil producers and conservationists. The coalition would develop airborne teams that would respond to oil spills within 12 hours. Team equipment would include items for cleaning wildlife and pumps for oil.

Old-growth forest

The trees stand tall and thick of girth. The air about them is cool and moist. The **soil** is rich and matted by a thick organic blanket. People marvel at the forest, imbibing its grandeur, coveting its timber. In another area, across the mountains, perhaps, the trees stand stooped and scraggly. The air about them is parched. The soil is coarse, barren, and hardened to the elements. People pass by the forest, ignoring its dignity, rejecting its worth.

These images reflect extremes in old-growth forests. The first is the compelling one: it exemplifies the common perception of a **ecosystem** at the center of a bitter environmental controversy. The second depicts an equally valid old-growth forest, but it is one whose fate few people care to debate.

The controversy over old-growth forests is the result of competition for what has become a scarce natural resource—large, old trees that can be either harvested to produce high value lumber products or preserved as notable relics as a forest proceeds through its stages of ecological **succession**. This competition is a classic environmental struggle, impelled by radically different perceptions of value and conflicting goals of consumptive and nonconsumptive use.

What is an old-growth forest? Before the modern debates, the definition seemed simple. Old-growth was a mature virgin forest; it consisted of giant old trees, many past their prime, which towered over a shady, multilayered understory and a thick, fermenting forest floor. In contrast to second-growth timber, the stand never had been harvested. It was something that existed in the West, having long since been cut in the East.

Old-growth Douglas fir forest, Pacific Northwest. (Photograph by Tom and Pat Lesson. National Audubon Society Collection/Photo Researchers, Inc. Reproduced by permission.)

In the mid to late 1980s several professional and governmental organizations, including the **Society of American Foresters**, the U.S. **Forest Service**, and California's State Board of Forestry, began efforts to define formally "old-growth forest" and the related term "ancient forest" for eco-

logical and regulatory purposes. The task was complicated by the great diversity in forest types, as well as by different views of the purpose and use of the definition. For example, 60 years of age might be considered old for one type, whereas 200 or 1,000 years might be more accurate for other types. Moreover, forest attributes other than age are more important for the wellbeing of certain **species** which are dependent on forests commonly considered old growth, such as the **northern spotted owl** and marbled murrelet. Nonetheless, some common attributes and criteria were developed.

Old-growth forests are now defined as those in a late seral stage of ecological succession, based on their composition, structure, and function. Composition is the representation of plant species—trees, shrubs, forbs, and grasses—that comprise the forest. (Often, in referring to an old-growth stand foresters limit composition to the tree species present). Structure includes the concentration, age, size, and arrangement of living plants, standing dead trees (called "snags"), fallen logs, forest-floor litter, and stream debris. Function refers to the forest's broad ecological roles, such as **habitat** for terrestrial and aquatic organisms, a repository for genetic material, a component in the hydrologic and biogeochemical cycles, and a climatic **buffer**. Each of these factors vary and must be defined and evaluated for each forest type in the various physiographic regions, while accounting for differences in disturbance history, such as wildfires, landslides, hurricanes, and human activities. The problem of specifically defining and determining use of these lands is exceedingly complex, especially for managers of multiple-use public lands who often are squeezed between the opposing pressures of commercial interests, such as the timber industry, and environmental preservation groups. The modern controversy centers primarily around forests in the northwest of United States and Canada—forests consisting of virgin **redwoods**, Douglas firs, and mixed conifers.

As an example of old-growth characteristics, the Douglas-fir forests are characterized by large, old, live trees, many more than 150 feet (46 m) tall, 4 ft (1.2 m) in diameter, and 200 years old. Interspersed among the trees are snags of various sizes—skeletons of trees long dead, now home to birds, small climbing mammals, and insects. Below the giants are one or more layers of understory—subdominant and lower growing trees of the same or perhaps different species, and beneath them are shrubs, either in a thick tangle providing dense cover and blocking passage or separated and allowing easy passage. The trees are not all healthy and vigorous. Some are malformed, with broken tops or multiple trunks, and infected by fungal rots whose conks protrude through the bark. Eventually, these will fall, joining others that fell decades or centuries ago, making a criss-cross pattern of rotting logs on the forest floor. In places, high in the trees, neighboring crowns touch all around, permanently shading the ground; elsewhere, gaps in the canopy allow sunlight to reach the forest floor.

Proponents of harvesting mature trees in old-growth forests assert that the forests cannot be preserved, that they have reached the **carrying capacity** of the site and the stage of decadence and declining productivity that ultimately will result in loss of the forests as well as their high commercial value which supports local lumber-based economies. They feel that society would be better served by converting these aged, slow-growing ecosystems to healthy, productive, managed forests. Management proponents also argue that adequate old-growth forests are permanently protected in designated wildernesses and national and state parks. Moreover, they point out that even though most old-growth forests are on **public land**, many forests are privately owned, and that land owners not only pay taxes on the forests, but they also have made an investment from which they are entitled a reasonable profit. If the forests are to be preserved, land owners and others suffering loss from the preservation should be reimbursed.

Proponents of saving the large old trees and their environments claim that the forests are dynamic, that although the largest, oldest trees will die and rot, they also will be returned to earth to support new growth, foster biological diversity, and preserve genetic linkages. Moreover, protection of the forests will help ensure survival of dependent species, some of which are threatened or endangered. Defenders claim that the trees will not be wasted; they simply will have alternative value. They believe that their cause is one of moral as well as biological imperative. More than 90% of America's old-growth forests have been logged, depriving **future generations** of the scientific, social, and psychic benefits of these forests. As a vestige of North American heritage, the remaining forests, they believe, should be manipulated only insofar as necessary to protect their integrity and minimize threats of natural fire or disease from spreading to surrounding lands. *See also* American Forestry Association; Endangered species; National forest; National Forest Management Act; Restoration ecology

Oligotrophic

The term oligotrophic is derived from the Greek term meaning "poorly nourished" and refers to an aquatic system that has low overall levels of primary production, principally because of low concentrations of the nutrients that plants require. The bottom waters of an oligotrophic lake do not become depleted of oxygen in summer, when rates of **primary productivity** in surface waters of the lake are typically at their highest. Oligotrophic bodies of water tend to have a more diverse community of **zooplankton** than waters with high levels of primary production. The term can also be used to describe any organism that only needs a limited supply of nutrients, or an insect that only utilizes a few plants as **habitat**.

[*Marie H. Bundy*]

Frederick Law Olmsted Sr. (1822 – 1903)

American landscape designer

The famous landscape designer of Central Park (on which he collaborated with the architect Calvert Vaux), Frederick Law Olmsted Sr. is widely known for that accomplishment alone. Considering the impact of the park on city life in New York, and on other designs around the world, that would be accomplishment enough. But Olmsted other achievements are so overshadowed by the Central Park project, that he is still not as well known in environmental circles as he should be.

Many people don't know, or are confused by, the fact that there were two Frederick Law Olmsteds: father and son, F. L. O Sr., and F. L. O Jr. Both of them were landscape architects, and F. L. O Jr. followed directly in his father's footsteps, assuming "leadership of the country's largest and most prestigious landscape architecture firm" after his father's death.

Olmsted Sr., was born in "the rural environs" of Hartford, Connecticut, the oldest son of a well-to-do merchant, from an old New England family. He was educated in a series of boarding schools in the rural Connecticut area where he grew up. More unorthodox educational benefits accrued from his apprenticeships as civil engineer and farmer along with his stint as a ship's cabin boy on a trip to China.

Reportedly, Olmsted's firm laid out some 1,000 parks in 200 cities. He also designed university campuses (U.C. Berkeley, Harvard, Amherst, Yale, etc.), cemeteries, hospital grounds (including the grounds for the hospital where he died, unhappy—even while suffering a terminal illness—that his plans for the hospital had not been followed carefully enough). A source of unhappiness in general was the fact that many of his plans were modified in ways he did not agree with (e.g., Stanford University), or even suppressed, as happened with his plan for **Yosemite National Park**.

The crown jewel of Olmsted's creativity is, of course, Central Park in New York City. As Bill Vogt describes it: "the entire area was man-made, literally from the ground up. It sprang from an 843-acre eyesore of stinking quagmire, rubbish heaps, rocky outcroppings, and squatters shacks." An army of workers created a lake, shoveled in enormous quantities of top **soil** to create natural-appearing meadows, and planted whole forests to screen the park from the city. Charles McLaughlin, the editor of Olmsted's papers, claimed that one of the reasons Olmsted was virtually forgotten for so long was that his designs have an "always been there" quality, resulting in landscapes that today "in their maturity...appear so 'natural' that one thinks of them as something not put there by artifice but merely preserved by happenstance." What Olmsted and Vaux created stands today as an oasis and respite from what Olmsted described as the city's "constantly repeated right angles, straight lines, and flat surfaces."

Among Olmsted's lesser known accomplishments were both his role in the Commission to establish Yosemite Park (a task undertaken in 1864, long before **John Muir** first saw Yosemite Valley) and preserve Niagara Falls, a movement which resulted in creation of the Niagara Falls State Reservation in 1888. He also was a prominent participant in the campaign to preserve the Adirondack region in upstate New York.

Even less well known are his writings not directly associated with landscape architecture or ecological design. Olmsted was quite an accomplished travel writer, producing still readable books like a *Saddle-trip on the Southwestern Frontier of Texas*, or his first book titled *Walks and Talks of an American Farmer in England*. Olmsted's travels in the South were as a roving journalist for the *New York [Daily] Times*; he was an acute observer and his travel books on the south were also commentaries on the institution of slavery (that he believed "to be both economically ruinous and morally indefensible.") Books from this period included *The Cotton Kingdom: A Traveler's Observations on Cotton and Slavery in the American Slave States*, *A Journey in the Seaboard Slave States*, and *Slavery and the South, 1852–1857*. He was also a founder of the liberal journal of commentary, *The Nation.* He never dissociated his design work from its social context (believing, in his words, that his works should have "a manifest civilizing effect"), and his biggest disappointments

occurred when he was not allowed to incorporate his ideas on social change into his various designs.

Open marsh water management

Open Marsh Water Management (OMWM) refers to the practice of controlling the mosquito population in salt marshes by creating an appropriate **habitat** for the natural enemies of the mosquitoes; and by reducing **flooding** in areas that are not wet on an ordinary basis—thus reducing an **environment** that would support mosquitoes but not their predators. Without use of **chemicals** that might be harmful to the **natural resources** surrounding the water body, as well as harmful to **wildlife** and humans, OMWM calls on nature's own ecological balance in order to successfully alter the pest—mosquito. The techniques were eventually employed by individuals and municipalities in order to control mosquitoes even in their own backyards, no matter how far that might be from tidal **wetlands**.

Before this plan was developed, and first used in New Jersey to control the mosquito problem in their tidal wetlands and marshes, the normal practice utilized a network of ditches. Under this method, which started around the time of the Civil War, the shallow ponds and water pools, the natural habitats of the birds and fish that fed on mosquitoes were changed or destroyed through ditch digging to drain the marshes and remove standing water. According to the *Conservationist* in an article published in June 1997, the digging also created a problem because, "Spoil generated by the ditch digging was often disposed of in marsh areas, creating high areas. The high areas were soon invaded by reeds and shrubs—vegetation of lesser value for marsh wildlife. In addition **spoil** mounds restricted the ebb and flow of tides, reducing flushing and creating habitat that actually favored mosquitoes. Many marshes became cut off from tidal flow, causing them to gradually become less saline [salty]. This resulted in changes in the composition of **flora** and **fauna**, enabling such non-native plants as the common reed (Phragmites) to invade the marsh. While somewhat attractive and often collected for dry plant arrangments, this plant has little wildlife value and displaces other more valuable species."

The key to OMWM is creating a habitat for one particular mosquito predator, the mummichogs, or marsh killfish. By restoring the body of water to its natural state, marsh killfish are provided with a habitat for survival, as are other fish and wildlife. The killfish are small but have appetites for mosquito larvae that never subside. Natural habitats are created by the tidal flow that go between being pools of deep water and shallow ponds. Killfish thrive under these conditions—laying their eggs when it is dry, and hatching them when it floods. The mosquito produces a vast number of larvae (all waiting to emerge as mosquitoes) as soon as the marshes are once again full of water. Yet simply producing more killfish does not ensure that they will reach the mosquitoes, and thus control the population. Again, the *Conservationist* has pointed out that, "For a project to be effective over a wide tidal range, the design of the tidal channels must be carefully tailored to the specific conditions of the marsh. Shallow access channels are constructed to allow the fish access to all parts of the marsh surface. However, pool and ditch sections must provide enough water and adequate depth to prevent excessive predation of the fish by wading birds."

Mosquito control in history

The state of New Jersey was the first place where OMWM was used—and the reasons for that go as far back as the early settlers. According to the *New Jersey Mosquito Homepage (NJMH)* Yellow Fever, contracted from mosquitoes, was the known as the "American plague," infecting the Massachusetts colony as early as 1647. In 1793, Philadelphia was hit and the city's population was devastated. When an army surgeon named **Walter Reed** finally traced the **virus** to the mosquito, *Aedes aegypti*, in 1900, the disease was dealt a death blow like the one it once had wagered on its victims. But the mosquito remained more than a simple annoyance that even the window screen introduced in the 1880s could not totally erase. Humans could contract **Eastern Equine Encephalitis** through mosquitoes, a disease of

epidemic proportions even into the middle half of the twentieth century. Horses continue to be infected if they are not inoculated against the disease. Mosquitoes can also transmit heartworm disease to dogs. Even in modern-day America, a variety of the **species** has been found to infect humans with the deadly **West Nile Virus** causing illness and death to wildlife and people from New York to Ohio, and down the east coast, by 2002.

The *NJMH* elaborates further on the history of mosquito control as an early priority in that state, and others. "Considerable public debate was given to the question whether mosquitoes could ever be controlled. Mosquito control operations grew in some towns but not in all towns. Newspaper battles raged when it was painfully noted that mosquitoes ignored municipal and even state borders. Local boards of health funded most of the extermination work. Laws in 1906 required support for local efforts from the state experiment station. Another law in 1912 directed the creation of county mosquito extermination commissions to assure full-time mosquito work With an increase in mosquito control workers and their rapid progress, it became clear than an organization was needed within which these workers could discuss their problems and share their experiences." Following the first convention of county commission in February 1914 in Atlantic City, the permanent organization known as the **New Jersey Mosquito Extermination Association** was formed. In 1935, a regional organization was formed with ten other states, the **Eastern Association of Mosquito Control Workers**, from a meeting at Trenton; it was re-named in 1944. The **American Mosquito Control Association** remains the premier organization concerned with mosquito control.

The common salt marsh mosquitoes include those known as *Aedes sollicitans*; *Aedes contator*,; and, *Aedes taeniorhynchus.* Adult females deposit their eggs on the marsh surface, which dry for 24 hours. The egg-filled depressions fill with water during the monthly high tides when the marsh is flooded, causing the larvae to hatch quickly. In addition to killfish acting as predators for the larvae, they can be controlled through the OMWM technique of utilizing a series of ditches to connect mosquito breeding depressions to more permanent bodies of water. It eliminates standing water, and also provides for predator fish to reach any mosquito larvae that is still there.

One example of a project to turn around the results of the former ditch digging practice that had been used and proven harmful(see History of to the natural environment is a research project operating in 2000, and supervised by the U.S. **Fish and Wildlife Service** (USFWS), Region 5, at the Rachel Carson **Wildlife Refuge** in Maine. The **U.S. Department of the Interior**, U.S. **Geological Survey** information system project of the Patuxent Wildlife Research Center in Laurel, MD provided a history and description of the project. "By the 1930s, most salt marshes throughout the northeastern United States had been ditched for mosquito control purposes. Documented impacts of this extensive network of ditching include **drainage** of marsh pools, lowered **water table** levels, vegetation changes, an associated trophic [feeding] responses. To restore the ecological functions of ditched salt marshes, while maintaining effective mosquito control, the USFWS (Region 5) is in the process of plugging the salt marsh ditches and establishing marsh pools. Ditch plugging is an adaptation of the mosquito control practice known as Open Marsh Water Management. The purpose of this proposed study is to compare and evaluate marshes that have been ditch plugged with unditched and parallet ditched marshes. Physical (tidal **hydrology**, water table level), chemical (**soil salinity**), and ecological (vegetation, **nekton**, marsh invertebrates, waterbirds, mosquito production) factors will be evaluated." Before data could be collected, whatever the results, this study was expected to create an established pattern for long-term salt marsh monitoring.

East coast states, as well as areas around the country, have engaged in OMWM not merely for simple mosquito control; but as a part of the restoration of **estuaries** and other **wildlife management** and restoration projects. OMWM techniques were still being refined as of 2002 as part of a return to an ecologically-balanced system that provides for the survival of natural resources, and for the survival of humans and wildlife.

Open system

The relationship between any system and its surrounding **environment** can be described in one of three ways. In an isolated system, neither matter nor energy is exchanged with its environment. In a closed system, energy, but not matter, is exchanged. In an open system, both matter and energy are exchanged between the system and its surrounding environment. Any **ecosystem** is an example of an open system. Energy can enter the system in the form of sunlight, for example, and leave in the form of heat. Matter can enter the system in many ways. Rain falls upon it and leaves by evaporation or streamflow, or animals migrate into the system and leave in the form of decay products.

Opportunistic organism

Opportunistic organisms commonly refer to animals and plants that tolerate variable environmental conditions and food sources. Some opportunistic **species** can thrive on almost any available **nutrient** source: omnivorous rats, bears, and raccoons are all opportunistic feeders. Many opportunists flourish under varied environmental conditions: the common house sparrow (*Passer domesticus*) can survive both in the warm, humid **climate** of Florida and in the cold, dry conditions of a Midwestern winter. Aquatic opportunists, often aggressive fish species, fast-spreading **plankton**, and water plants, frequently tolerate fluctuations in water **salinity** as well as temperature.

A secondary use of the term "opportunistic" signifies species that can quickly take advantage of favorable conditions when they arise. Such species can postpone reproduction, or even remain dormant, until appropriate temperatures, moisture availability, or food sources make growth and reproduction possible. Some springtime-breeding lizards in Australian deserts, for example, can spend months or years in a juvenile form, but when temperatures are right and a rare rainfall makes food available, no matter what time of year, they quickly mature and produce young while water is still available. More familiar opportunists are viruses and bacteria that reside in the human body. Often such organisms will remain undetected with a healthy host for a long time. But when the host's immune system becomes weak, resident viruses and bacteria seize an opportunity to grow and spread. Thus people suffering from malnutrition, exhaustion, or a prolonged illness are especially vulnerable to common opportunistic diseases such as the common cold or pneumonia.

Adaptable and prolific reproductive strategies usually characterize opportunistic organisms. While some plants can reproduced only when pollinated by a specific, rare insect and many animals can breed only in certain conditions and at a precise time of year, opportunistic species often reproduce at any time of year or under almost any conditions. House mice (*Mus musculus*) are extremely opportunistic breeders: they can produce sizeable litters at any time of year. Opportunistic feeding aids their ability to breed year round; these mice can nourish their young with almost any available vegetable matter, fresh or dry.

The common dandelion (*Taraxacum officinale*) is also an opportunistic breeder. Producing thousands of seeds per plant from early spring through late fall, the dandelion can reproduce despite **competition** from fast-growing grass, under heavy applications of chemical herbicides, and even with the violent weekly disturbance of a lawn mower. Once mature, dandelion seeds disperse rapidly and effectively, riding on the wind or on the fur of passing rodents. The common housefly (*Musca domestica*) is also an opportunistic feeder and reproducer—it can both feed and lay eggs on almost any organic material as long as it is fairly warm and moist.

Because of their adaptability, opportunistic organisms commonly tolerate severe environmental disturbances. Fire, floods, **drought**, and **pollution** disturb or even eliminate plants and animals that require stable conditions and have specialized nutrient sources. Fireweed (*Epilobium angustifolium*), an opportunist that readily takes advantage of bare ground and open sunlight, spreads quickly after land is cleared by fire or by human disturbance. Because they tolerate, or even thrive, in disturbed environments, many opportunists flourish around human settlements, actively expanding their ranges as human activity disrupts the **habitat** of more sensitive animals and plants. Opportunists are especially visible where chemical pollutants contaminate habitat. In such conditions overall species diversity usually declines, but the population of certain opportunistic species may increase as competition from more sensitive or specialized species is eliminated.

Because they are tolerant, prolific, and hardy, many opportunistic organisms, including the house fly, the house mouse, and the dandelion, are considered pests. Where they occur naturally and have natural limits to their spread, however, opportunists play important environmental roles. By

quickly colonizing bare ground, fireweed and opportunistic grasses help prevent **erosion**. Cottonwood trees (*Populus spp.*), highly opportunistic propagators, are among the few trees able to spread into **arid** regions, providing shade and nesting places along stream channels in deserts and dry plains. Some opportunists that are highly tolerant of pollution are now considered indicators of otherwise undetected **chemical spills**. In such hard-to-observe environments as the sea floor, sudden population explosions among certain bottom-dwelling marine mollusks, plankton, and other invertebrates have been used to identify **petrochemical** spills around drilling platforms and shipping lanes. *See also* Adaptation; Contaminated soil; Environmental stress; Flooding; Growth limiting factors; Indicator organism; Parasites; Resilience; Scavenger; Symbiosis

Orangutan

The orangutan (*Pongo pygmaeus*), one of the Old World great apes, has its population restricted to the rain forests of the Indonesian islands of Sumatra and Borneo. The orangutan is the largest living arboreal mammal, and it spends most of the daylight hours moving slowly and deliberately through the forest canopy in search of food. Sixty percent of their diet consists of fruit, and the remainder is composed of young leaves and shoots, tree bark, mineral-rich **soil**, and insects. Orangutans are long-lived, with many individuals reaching between 50 and 60 years of age in the wild. These large, chestnut-colored, long-haired apes are facing possible **extinction** from two different causes: **habitat** destruction and the wild animal trade.

An orangutan. (Photograph by Tim Davis. Photo Researchers Inc. Reproduced by permission.)

The **rain forest ecosystem** on the islands of Sumatra and Borneo is rapidly disappearing. Sumatra loses 370 mi^2 (960 km^2) of forest a year, or about 1.6%, faster than any other Indonesian island. The rest of central Indonesia, of which Borneo comprises a major part, loses about 2,700 square miles (7,000 km^2) per year. Some experts believe this

estimate is too low, and they argue it could be closer to 4,600 mi^2 (12,000 km^2) per year. Another devastating blow was dealt Borneo's rain forests just over a decade ago, when more than 15,400 mi^2 (40,000 km^2) of the island's tropical forest was destroyed by **drought** and fire between 1982 and 1983. The fire was set by farmers who claimed to be unaware of the risks involved in burning off vegetation in a drought stricken area. Even though Indonesia still has over 400,000 mi^2 (1,000,000 km^2) of rain forest habitat remaining, the rate of loss threatens the continued existence of the wild orangutan population, which is now estimated at about 25,000 individuals.

Both the Indonesian government and the **Convention on International Trade in Endangered Species of Wild Fauna and Flora** (CITES) have banned international trade of orangutans, yet their population continues to be threatened by the black market. In order to meet the demand for these apes as pets around the world, poachers kill the mother orangutan to secure the young ones, and the **mortality** rate of these orphans is extremely high, with less than 20% of those smuggled ever arriving alive at their final destination. This high mortality rate is directly due to stress, both emotional and physiological, on the young orangutans. The **transportation** scheme involved in smuggling these animals out of Indonesia to major trade centers throughout the world is intricate and time-consuming, and the way in which they are concealed for shipping is inhumane. These are two more reasons why only one out of five or six orangutan babies will survive the ordeal.

Some hope for the **species** rests in a global effort to manage a captive propagation program in zoos. A potentially self-sustaining captive population of more than 850 orangutans has been established. An elaborate system of networking and recording of all legally held individuals may also aid in the recognition and recapture of smuggled animals. Researchers have also developed methods of determining whether smuggled orangutans are of Bornean or Sumatran origin, thus providing a means of maintaining genetic integrity for those that can be bred in captivity or relocated.

Order of magnitude

A mathematical term used loosely to indicate tenfold differences between values. This concept is crucial to interpreting logarithmic scales such as **pH** or **earthquake** magnitude, where each number differs by a factor of 10, and two numbers differ by a factor of 100 (10 times 10). For example, a pH of 4 is 100 times as acidic as a pH of 6 because they differ by two orders of magnitude. Scientists often generalize with this term; for example "our ability to measure pollutants has improved by several orders of magnitude" means that whereas before we were able to measure **parts per million** (ppm), we can now measure **parts per billion** (ppb).

Oregon silverspot butterfly

The Oregon silverspot butterfly (*Speyeria zerene hippolyta*) is a medium-sized butterfly, predominantly orange and brown with black veins and spots on its hindwings and bright silver spots on its forewings. The length of its forewings is about 1.1 in (2.9 cm). The female is usually slightly larger than the male. This butterfly is listed as threatened by the U. S. **Fish and Wildlife Service** and has been protected under the **Endangered Species Act** since 1980.

Inhabiting a very restricted range, the Oregon silverspot occurs only in salt spray meadows along the Pacific coast in Oregon and Washington. This **habitat** is characterized by heavy rainfall, fog, and mild temperatures. The most critical feature of this habitat, however, is the presence of the western blue violet (*Viola adunca*), the host plant of the butterfly's larva. For two months each spring, larval Oregon silverspots feed on violet leaves before entering the pupa stage of development. This butterfly was historically present at 17 locations along the coasts of Oregon and Washington, but now only five populations in Oregon are known to exist with certainty.

Housing developments and recreational uses of the coast that destroy or degrade butterfly habitat are the major threats to this subspecies's survival. Natural fire patterns in its meadow habitat have been suppressed, allowing nonnative vegetation to mix with native plants and changing the habitat's character. An area of Lane County, Oregon with a healthy population of Oregon silverspots has been designated **critical habitat** for this subspecies. Expansion of the population of western blue violets in this area will be encouraged by the control of saplings and other invading plants. Transplantation of western blue violets to other sites with suitable meadow habitat may also be attempted. A recovery plan was put into effect in 1999 and monitored through 2000. It was headed by Lewis and Clark College, the Oregon Zoo in Portland, and the Woodland Park Zoo in Seattle and consisted of rearing the larvae in captivity,

Oregon silverspot butterfly (Speyeria zerene hippolyta). (Photograph by Paul A. Opler. Reproduced by permission.)

then returning the butterflies to the wild. Although the Oregon silverspot butterfly is not in immediate danger of **extinction**, its specific habitat requirements and the vulnerability of that habitat to degradation and destruction, makes intervention necessary to ensure the long-term survival of this subspecies.

Organic gardening and farming

Agriculture has changed dramatically since the end of World War II. As a result of new technologies, mechanization, increased chemical use, specialization, and government policies, food and fiber productivity has soared. While some of these changes have led to positive effects, there have been significant costs: **topsoil** depletion, **groundwater** contamination, harmful **pesticide residue**, the decline of family farms, and increasing costs of production. To counterbalance these costs, there is a growing movement to grow plants organically.

On a local level, suburban homeowners and city dwellers are finding ways to plant their own food for personal consumption in plots that are not sprayed with **chemicals** or treated with synthetic fertilizers. City dwellers may team up to work a collective, organic garden on a vacant lot. Homeowners have the option to create **mulch** piles—a mixture of leaves and organic materials, vegetable leavings, egg shells, coffee grounds, etc.—that eventually become a rich **soil**, thanks to the breakdown of these elements by tiny organisms. This enriched soil becomes a fertile, clean foundation for a bountiful garden. The inevitable weeds that grow can be picked by hand.

On a larger level, emerging as an answer to some of these farming problems is a movement called "sustainable agriculture." Sustainability rests on the principle that we must meet the needs of the present without compromising the ability of **future generations** to meet their own needs.

Organic farming is part of this movement. Most significantly, organic foods are grown without synthetic fertilizers, pesticides, or herbicides. Organic farming and gardening is the result of the belief that the best food crops come from soil that is nurtured rather than treated. Organic farmers take great care to give the soil nutrients to keep it healthy, just as a person works to keep his or her body healthy with certain nutrients. Thus, organic farmers prefer to provide those essential soil builders in natural ways: using cover crops instead of chemical fertilizers, releasing predator insects rather than spraying pests with pesticides and hand weeding rather than applying herbicides.

Organic production practices involve a variety of farming applications. Specific strategies must take into account **topography**, soil characteristics, **climate**, pests, local availability of inputs, and the individual grower's goals. Despite the site-specific and individual nature of this approach, several general principles can be applied to help growers select appropriate management practices. Growers must:

1. Select **species** and varieties of crops that are well suited to the site and to the conditions of the farm.

2. Diversify the crops, including livestock and cultural practices, to enhance the biological and economic **stability** of the farm.

3. Manage the soil to enhance and protect its quality.

Making the transition to **sustainable agriculture** is a process. For farmers, the transition normally requires a series of small, realistic steps. For example in California, where there has been a water shortage, steps are being taken to develop drought-resistant farming systems, even in normal years. Farmers are encouraged to improve **water conservation** and storage measures, provide incentives for selecting specific crops that are drought-tolerant, reduce the volume of **irrigation** systems, and manage crops to reduce water loss.

In order to stop soil **erosion**, farmers are encouraged to reduce or eliminate tillage, manage irrigation to reduce **runoff**, and keep the soil covered with plants or mulch.

Farmers are also encouraged to diversify, since diversified farms are usually more economically and ecologically resilient. By growing a diversity of crops, farmers spread economic risk and the crops are less susceptible to the infestation of certain predators that feed off one crop. Diversity can buffer a farm biologically. For example, in annual cropping systems, crop rotation can be used to suppress weeds, pathogens, and insect pests.

Cover crops can have a stabilizing effect on the agro-**ecosystem**. Cover crops hold soil and nutrients in place, conserve soil moisture with mowed or standing dead mulches, and increase the water **infiltration** rate and soil water holding capacity. Cover crops in orchards and vineyards can buffer the system against **pest** infestations by increasing beneficial arthropod populations and can therefore reduce the need for chemicals. Using a variety of cover crops is also important in order to protect against the failure of a particular species to grow and to attract and sustain a wide range of beneficial arthropods.

Optimum diversity may be obtained by integrating both crops and livestock in the same farming operation. This was the common practice for centuries until the mid-1900s, when technology, government policy, and economics compelled farms to become more specialized. Mixed crop and livestock operations have several advantages. First, growing row crops only on more level land and pasture or forages on steeper slopes will reduce soil erosion. Second, pasture and forage crops in rotation enhance soil quality and reduce erosion; livestock manure in turn contributes to soil fertility. Third, livestock can buffer the negative impacts of low rainfall periods by consuming crop residue that in "plant only" systems would have been considered failures. Finally, feeding and marketing are more flexible in animal production systems. This can help cushion farmers against trade and price fluctuations and, in conjunction with cropping operations, make more efficient farm labor.

Animal production practices are also sustainable or organic. In the midwestern and northeastern United States, many farmers are integrating crop and animal systems, either on dairy farms or with range cattle, sheep, and hog operations. Many of the principles outlined in the crop production section apply to both groups. The actual management practices will, of course, be quite different.

Animal health is crucial, since unhealthy stock waste feed and require additional labor. A herd health program is critical to sustainable livestock production. Animal nutrition is another major issue. While most feed may come from other enterprises on the ranch, some purchased feed is usually imported. If the animals feed from the outside, this feed should be as free of chemicals as possible.

A major goal of organic farming is a healthy soil. Healthy soil will produce healthy crops and plants that have optimum vigor and less susceptibility to pests. In organic or sustainable systems, the soil is viewed as a fragile and living medium that must be protected and nurtured to ensure its long-term productivity and stability. Fertilizers and other inputs may be needed, but they are minimized as the farmer relies on natural, renewable, and on-farm inputs.

While many crops have key pests that attack even the healthiest of plants, proper soil, water, and **nutrient** management can help prevent some pest problems brought on by crop stress or nutrient imbalance. Additionally, crop management systems that impair soil quality often result in greater inputs of water, nutrients, pesticides, and/or energy for tillage to maintain yields.

Sustainable approaches are those that are the least toxic and least energy intensive and yet maintain productivity and profitability. Farmers are encouraged to use preventive strategies and other alternatives before using chemical inputs from any source. However, there may be situations where the use of synthetic chemicals would be more "sustainable" than a strictly nonchemical approach or an approach using toxic "organic" chemicals. For example, one grape grower in California switched from tillage to a few applications of a broad spectrum contact **herbicide** in his vine row. This approach may use less energy and may compact the soil less than numerous passes with a cultivator or mower.

Coalitions have been created to address the growing organic movement concerns on a local, regional, and national level. The Organic Food Production Association of North America is the trade and marketing arm of the organic industry in the United States and Canada. The Farm Bill of 1990—Organic Foods Production Act—addressed the growing organic farming movement. Title 21 of the bill is the section that will be dealing with the regulations regarding organic certification. The **U.S. Department of Agriculture**, with the guidance of an advisory committee or National Organic Standards Board, is in the process of establishing the federal regulations that will standardize the rules for the entire organic industry in the United States, from growing and manufacturing to distribution. Presently, the organic movement includes growers, retailers, distributors, traders, urban and individual consumers, processors, and various nonprofit organizations nationwide.

Until the regulations are in place, the standards established by individual states vary, or in some states do not exist at all. The 1990 law requires that organic farmers wait for three years before they are officially certified—to ensure most of the chemicals have been eliminated. With proper documentation, on-site inspectors are then able to certify the farm. Organic groups admit that no organic program can claim absolutely it is residue free. The issue here is a process—of farming and producing product in as chemically free and healthy an **environment** as is possible.

The international community is joining the organic movement. Europe—the European Common Market—Australia, Argentina, and many countries in South America are establishing their own organic standards and have joined together under the organization called International Federation of Organic Agricultural Movements.

In addition to the upcoming United States federal standardization of organic farming, more policies are needed to promote simultaneously **environmental health** and economic profitability.

For example, commodity and price support programs could be restructured to allow farmers to realize the full benefits of the productivity gains made possible through alternative practices. Tax and credit policies could be modified to encourage a diverse and decentralized system of family farms rather than corporate concentration and absentee ownership. Government and land grant university research could be modified to emphasize the development of sustainable alternatives. Congress can become more rigorous in preventing the application of certain pesticides, especially those that have been shown to be carcinogenic. Marketing orders and cosmetic standards (i.e. color and uniformity of product, etc.) could be amended to encourage reduced **pesticide** use.

Consumers play a key role. Through their purchases, they send strong messages to producers, retailers, and others in the system about what they think is important. Food cost and nutritional quality have always influenced consumer choices. The challenge now is to find strategies that broaden consumer perspectives so that environmental quality and resource use are also considered in shopping decisions. Coalitions organized around improving the food system are one specific method of systemizing growing and delivery for the producers, retailers, and consumers.

"Clean" meat, vegetables, fruits, beans, and grains are available, as are products such as organically grown cotton. As consumer demands increase, growers will respond. *See also* Biodiversity; Monoculture

Organic waste

Organic wastes contain materials which originated from living organisms. There are many types of organic wastes and they can be found in **municipal solid waste**, industrial **solid waste**, agricultural waste, and wastewaters. Organic wastes are often disposed of with other wastes in landfills or incinerators, but since they are **biodegradable**, some organic wastes are suitable for **composting** and land application.

Organic materials found in municipal solid waste include food, paper, wood, sewage **sludge**, and **yard waste**. Because of recent shortages in **landfill** capacity, the number of municipal composting sites for yard wastes is increasing across the country, as is the number of citizens who compost yard wastes in their backyards. On a more limited basis, some mixed municipal waste composting is also taking place. In these systems, attempts to remove inorganic materials are made prior to composting.

Some of the organic materials in municipal solid waste are separated before disposal for purposes other than composting. For example, paper and cardboard are commonly removed for **recycling**. **Food waste** from restaurants and grocery stores is typically disposed of through **garbage** disposals, therefore, it becomes a component of **wastewater** and sewage sludge.

A large percentage of sewage sludge is landfilled and incinerated, but it is increasingly being applied to land as a **fertilizer**. Sewage sludge may be used as an agricultural fertilizer or as an aid in reclaiming land devastated by **strip mining**, **deforestation**, and over-application of inorganic fertilizers. It may also be applied to land solely as a means of disposal, without the intention of improving the **soil**.

The organic fraction of industrial waste covers a wide spectrum including most of the components of municipal organic waste, as well as countless other materials. A few examples of industrial organic wastes are papermill sludge, meat processing waste, brewery wastes, and textile mill fibers. Since a large variety and volume of industrial organic wastes are generated, there is a lot of potential to recycle and compost these materials. Waste managers are continually experimenting with different "recipes" for composting industrial organic wastes into soil conditioners and soil amendments. Some treated industrial wastewaters and sludges contain large amounts of organic materials and they too can be used as soil fertilizers and amendments.

Production of biogas is another use of organic waste. Biogas is used as an alternative energy source in some **third world** countries. It is produced in digester units by the **anaerobic decomposition** of organic wastes such as manures and crop residues. Beneficial byproducts of biogas production include sludges that can be used to fertilize and improve soil, and the inactivation of pathogens in the waste. In addition, there is ongoing research on using organic wastes in developing countries: (1) in fish farming; (2) to produce algae for human and animal consumption, fertilizer, and other uses; and (3) to produce aquatic macrophytes for animal feed supplements.

Organization of Petroleum Exporting Countries

Established in 1960 by Iran, Iraq, Kuwait, and Venezuela, the Organization of **Petroleum** Exporting Countries (OPEC) was created to control the price of oil by controlling the volume of production. Modeled on the Texas Railroad Commission in the United States, the group was also intended to make other decisions about petroleum policy and to provide technical and economic support to its members. Indonesia, Libya, Qatar, Algeria, Nigeria, Saudi Arabia, and the United Arab Emirates have been admitted since 1960, and it is now estimated that the nations in OPEC control nearly three-quarters of the world's oil reserves.

In October 1973, members of OPEC met at their headquarters in Vienna and voted to raise oil prices by 70%. OPEC is dominated by oil-producing countries from the Middle East, and this decision was designed to retaliate against Western support of Israel during its war with Egypt. At a conference in Tehran, Iran, in December of that same year, OPEC countries raised oil prices an additional 130%, and they enacted an embargo on shipments to the United States and the Netherlands. The Iranian revolution in 1979 further restricted the world supply of oil, intensifying the effects of OPEC policies; between 1973 and 1980, the price of a barrel of oil rose from three dollars to 35 dollars.

The steep rise in oil prices had a disruptive effect in the United States, which is the largest oil importer in the world. It had an ever greater economic impact on industrialized countries such as Japan, which have little or no petroleum reserves of their own. But the economies in **less developed countries** (LDC) were the hardest hit; the rising price of oil decreased their purchasing power, increasing their trade deficit as well as their level of debt. There was a rapid transfer of wealth to oil-producing countries during this period, with the annual income of OPEC countries increasing 22.5 billion dollars in 1973 to 275 billion dollars in 1980.

The organization was not, however, able to maintain its influence over the international oil market in the 1980s, and prices dropped to as low as 10 dollars a barrel during this decade. World oil consumption reached a peak in 1979, at a high of 66 million barrels a day, and then dropped sharply in the years that followed. Many Western countries were encouraging **conservation**; they had also invested in other sources of energy, most notably **nuclear power**. Oil exploration had resulted in discoveries in Alaska and the North Sea; Mexico and Soviet Union, oil-exporting countries that were not members of OPEC, had also become an increasingly important part of the international petroleum trade. As their power over the price of oil became more diffused, consensus within OPEC became more difficult, and these internal divisions were made worse by political conflicts within the Middle East, particularly the war between Iran and Iraq.

From an environmental perspective, the most important effect of the oil price shocks of the 1970s may have been how it changed world patterns of energy consumption. Though the increase in prices forced many countries to use **coal** and nuclear power despite the damage they can do to the **environment**, economic pressures also stimulated research into many **alternative energy sources**, such as **solar energy**, **wind energy**, and hydroelectric power. In the last decade of the twentieth century, the sudden decrease in oil prices limited the sense of urgency as well as the funding for many of these research projects, and some environmentalists have suggested that higher oil prices might be better for the environment and the global economy over the long term.

Organochloride

Usually refers to organochlorine pesticides, although it could also refer to any chlorinated organic compound. The organo-

chlorine pesticides can be classified by their molecular structures. The cyclopentadiene pesticides are aliphatic, cyclic structures made from Diels-Alder reactions of pentachlorocyclopentadiene, and include **chlordane**, nonachlor, heptachlor, heptachlor epoxide, dieldrin, aldrin, endrin, **mirex**, and **kepone**. Other subclasses of organochlorine pesticides are the DDT family and the hexachlorocyclohexane isomers. All of these pesticides have low solubilities and volatilities and are resistant to breakdown processes in the **environment**. Their toxicities and environmental persistence have led to their restriction or suspension for most uses in the United States. *See also* Organophosphate

Organophosphate

Refers to classes of organic compounds that are often used in insecticides. Many of the organophosphate pesticides were developed over the last 30 years to replace organochlorine insecticides. They generally have the highest solubilities and shortest half-lives of the common classes of pesticides, but tend to have higher acute toxicities. Organophosphates act by disrupting the central nervous system, specifically by blocking the action of the **enzyme** acetylcholinesterase, which controls nerve impulse transmission. Organophosphates can impact human health at moderate levels of exposure, causing disorientation, numbness, and tremors. Acute exposures can cause blindness and death. Well-known organophosphate pesticides include parathion, malathion, **diazinon**, and phosdrin. *See also* Cholinesterase inhibitor; Organochloride

David W. Orr (1944 –)

American environmental writer

In recent years, an effort has been undertaken to make every citizen numerate, that is, able to use mathematics at a level that is minimally functional in modern society. David Orr, and writers and thinkers of kindred mind, believe that for citizens to be minimally functional in the complex, interdependent world of the twenty-first century, they must go beyond literacy in language and beyond numeracy and attain also a certain level of ecological literacy.

Orr is best known for his 1992 book titled *Ecological Literacy* and for his brief editorial essays in the journal *Conservation Biology*, written from his position as education editor for that journal. Born in Des Moines, Iowa, and raised in New Wilmington, Pennsylvania, he holds degrees from Westminster College (BA), Michigan State University (MA), and the University of Pennsylvania (Ph.D. in International Relations). He was a professor of political science before becoming Professor and Chair of the Environmental Studies Program at Oberlin College in Ohio. He is well-known for his criticism of the **environmental degradation** brought about by the free market system, his critique of the American educational system, and his activist attempts to change both systems toward more ecologically sustainable behavior.

Though the free market system seems to be in the ascendancy today, Orr believes that capitalism "is failing because it produces too much and shares too little." He especially laments conservatives in the capitalist system who do not understand the history and meaning of what conservative means. He claims that a genuine conservatism would be **conservation** oriented and not intent, for example, on perpetual economic growth that "has become the most radicalizing force for change in the modern world."

Much of this failure in the western system he traces to an ecological crisis that "represents, in large measure, a failure of education." He faults every level of education in general for not teaching students how to learn, while in school and throughout life, and for failing to define knowledge adequately for postmodern life. Too many disciplines do not consider the interrelations between people and the earth on which they live. This failure, Orr claims, can "ultimately...be traced to our schools and to our proudest universities."

Much of Orr's work focuses on changing universities, to eliminate what he considers the nationwide campus emphasis on "fast knowledge," or "ignorant knowledge" that is "cut off from its ecological and social context." He laments the over-professionalization of the professorate, researchers who churn out fast knowledge and create students (and citizens) who are "knowledge technicians instead of broadly thoughtful, liberally educated persons." He relates narrowness and self-interest to "the problem of ecological denial," in which people cannot think in the long term or about the "large and messy questions" associated with environmental issues. Througout his career, Orr has received many awards such as an Honorary Doctorate in Humane Lettersfrom Arkansas College in 1990 and the Benton Box Award from Clemson University in 1995.

Orr believes that campus buildings even teach negative lessons: "the design, construction, and operation of academic buildings can be a liberal education in a microcosm that includes virtually every discipline in the catalog." Thus, he has undertaken what is proving to be a life-long campaign to change campuses to educational laboratories for ecological systems and environmental sustainability.

Henry Fairfield Osborn (1887 – 1969)

American conservationist and naturalist

Born in Princeton, New Jersey, Osborn was the son of a renowned paleontologist who was also president of the American Museum of Natural History. Osborn graduated from Princeton in 1909 and attended Cambridge University in England. He then held a variety of jobs, working in freight and railroad yards and serving as a soldier in World War I. He finally took a position at a bank dealing in Wall Street investments.

Throughout his life, Osborn had accompanied his father on paleontological expeditions. As these trips continued into his adulthood, Osborn realized that his true vocation lay not finance but in natural science. In 1935 he accepted a position as secretary of the New York Zoological Society, an organization devoted to the "instruction and **recreation** of the people of New York." He was named president of the Society five years later and remained in office until 1968. As president, he actively pursued the creation of the Marine Aquarium at Coney Island, New Jersey, as well as improvements to the Bronx Zoological Park.

Osborn recognized the crucial need for an organization that would foster the preservation of **endangered species** and their habitats. With this purpose in mind, he founded in 1947 the Conservation Foundation (CF), an adjunct of the New York Zoological Society. CF was absorbed in 1990 by the **World Wildlife Fund** which still works for the conservation of endangered **wildlife** and natural areas.

Osborn used his knowledge of **nature** and his positions within these organizations to influence policy in Washington. He served on the Conservation Advisory Committee of the **U.S. Department of the Interior** as well as on the Planning Committee of the Economic and Social Council of the United Nations.

Like **William Vogt** and later Paul R. Ehrlich, Osborn often expressed concern about **population growth** and available **natural resources**. He fully realized the serious ramifications of environmental and ecological neglect and understood the steps needed to conserve existing resources and develop improved methods of distribution. He published two highly successful books, *Our Plundered Planet* (1948) and *The Limits of the Earth* (1953), each of which outlined the importance of conservationist ideals and the perils of a population explosion. Osborn was an active member of the **Save-the-Redwoods League**, International Council for Bird Preservation, and other related organizations. He died in New York City in 1969 at the age of 82.

Our Common Future (Brundtland Report)

In late 1983 **Gro Harlem Brundtland**, the former Prime Minister of Norway, was asked by the Secretary-General of the United Nations to establish and chair the World Commission on **Environment** and Development, a special, independent commission convened to formulate "a global agenda for change."

The Secretary-General's request emerged from growing concern in the General Assembly about a number of issues, including: long-term **sustainable development**; cooperation between developed and developing nations; more effective international management of environmental concerns; the differing international perceptions of long-term environmental issues; and strategies for protecting and enhancing the environment.

The commission worked for three years and produced what is commonly known as "The Brundtland Report." Published in book form in 1987 as *Our Common Future*, the report addresses what it identifies as "common concerns," such as a threatened future, sustainable development, and the role of the international community. The report also examines "common challenges," including **population growth**, food security, **biodiversity**, and energy choices, as well as how to make industry more efficient. Finally, the report lists "common endeavours," such as managing the commons, maintaining peace and security while not sus-

pending development or degrading the environment, and changing institutional and legal structures. A chapter on each one of these concerns, challenges, and endeavors is included in the book.

Two years after publication of the report, Brundtland summarized its findings in a speech to the **National Academy of Sciences** in the United States. The reports's core concepts, she explained, were "that development must be sustainable, and the environment and world economy are totally, permanently intertwined." She went on to assert that these concepts "transcend nationality, culture, ideology, and race." She summarized by repeating the report's urgent warning: "Present trends cannot continue. They must be reversed."

The Brundtland Report issued a multitude of recommendations to help attain sustainable development and to address the problems posed by a global economy that is intertwined with the environment. The report recommends ways to deal with the debt crisis in developing nations, and insists on linking poverty and environmental deterioration: "A world in which poverty is endemic will always be prone to ecological and other catastrophes." The report also argues that security issues should be defined in environmental rather than military terms.

The members of the commission felt that a vast array of institutional changes were necessary if progress was to be made, and the report addresses these issues. It declares that the problems confronting the world are all tied together, "yet most of the institutions facing those challenges tend to be independent, fragmented, working to relatively narrow mandates with closed decision processes." Much of the work done by the commission focused on policy issues such as long-term, multifaceted population policies and ways to create effective incentive systems to encourage production, especially of food crops. Recommendations also include methods for a successful transition from **fossil fuels** to "low-energy" paths based on renewable resources.

The report repeatedly notes the differences between developed and developing nations in terms of energy use, **environmental degradation**, and urban growth, but it also emphasizes that "specific measures must be located in a wider context of effective [international] cooperation, if the problems are to be solved." The report always brings the problems back to people, to the importance of meeting basic human needs and the necessity of decreasing the disparities between developed and developing countries: "All nations will have a role to play in changing trends, and in righting an international economic system that increases rather than decreases inequality, that increases rather than decreases numbers of poor and hungry."

The report is not merely a grim listing of "ever increasing environmental decay, poverty, and hardship in an ever more polluted world among ever decreasing resources." Surprising to some, it is also a documentation of "the possibilities for a new era of economic growth," an on-going era of sustainable, non-destructive growth. *See also* Economic growth and the environment; Environmental economics; Environmental monitoring; Environmental policy; Environmental stress; Green politics; International Geosphere-Biosphere Programme; United Nations Earth Summit; United Nations Environment Programme; World Bank

Overburden

Refers to the rock and **soil** above a desired economic resource, such as **coal** or an ore body. It is normally associated with **surface mining**, in contrast to underground mining where **tailings** are a more common byproduct. The depth of overburden is a critical economic factor when assessing the feasibility of mining. Unless the **topsoil** is stored for later **reclamation**, overburden removal usually destroys this crucial resource, greatly magnifying the task of natural or cultural revegetation. In North America, overburden removal requires blasting through hard caprock, which leave landscapes resembling fields of glacial debris. *See also* Mine spoil waste

Overfishing

With the tremendous increase in the human population since the industrial revolution, there has been an ever increasing use and, often, exploitation of many of the world's **natural resources**. The demand for fish and shellfish has exemplified this misuse of natural resources. Paralleling the changes in agriculture, the fisheries industry has progressed from a small-scale, subsistence operation to a highly mechanized, ultra-efficient means of securing huge quantities of fish and shellfish to satisfy the burgeoning market demand. These industrialized commercial fisheries have allowed fishermen to easily work the far offshore waters, and more efficient refrigeration has allowed greater travel time, thus allowing for longer excursions.

Overfishing results in the removal of a substantial portion of a species' population so that there are too few

individuals left to reproduce and bring the population back to the level it was the year before. Overfishing has a tremendous negative impact on nontarget **species** as well. More than half, and occasionally as much as 90%, of a catch may be discarded, and this can adversely affect the **environment** by altering predator-prey ratios and adding excess **organic waste** through the dumping of nearly 30 million tons of dead or dying fish and shellfish overboard annually. Overfishing has also negatively impacted diving seabird, sea turtle, and dolphin populations since these animals often get trapped and killed in fishing nets. It is estimated that 44,000 albatrosses are killed each year by Japanese tuna fishermen, and that, over the years, tuna purse seine nets in the Eastern Tropical Pacific have caused the death of millions of **dolphins**.

The offshore waters are not regulated as are the coastal waters of our continents, therefore several populations of commercially important species have been overfished. Often, fishermen simply try to catch as many fish as possible (as fast as possible), because they believe that any fish left in the water will be caught by someone else. The codfish industry of the Atlantic coast of Canada and the United States had been a productive fishery since the time of the early settlers, hundreds of years ago. But with the introduction, in 1954, of a new kind of highly industrialized fishing vessel, the factory trawler, conditions changed for the cod population. In 1968, exceeding the normal catch for the region by over 500,000 tons, 810,000 tons of cod were taken off Labrador and the Grand Banks off Newfoundland. In the decade to follow, the cod population declined to the point that the number of spawning codfish off Newfoundland in 1977 showed a 94% decrease from the number in 1962. Another species to show population decline due to overfishing is the American shad, often referred to as the poor man's **salmon**. Harvested by Native Americans and the early colonists, the shad fishery was supplying one of the most commercially valuable fish to the region surrounding the **Chesapeake Bay** during the 1800's. Overfishing, combined with an increase in **pollution** and the disruption of spawning runs by the damming of rivers, took a fishery with an annual harvest of nearly 18 million pounds at the turn of the century to less than 2 million pounds in the 1970s.

A tragic example of the effect of overfishing is seen at **Georges Bank** in the Atlantic Ocean. Georges Bank, discovered by the Italian explorer Giovanni da Verrazano in the early part of the 16th century, was named after St. George by English settlers in 1605. Home to over 100 species of fish, Georges Bank has been a historically significant site of plentiful fishing for centuries. It is an ovoid embankment that is about 75 miles (120 km) off of the coast of New England. It encompasses an area 149 miles (240 km) in length and 75 miles (120 km) in width, and is over 330 feet (100 meters) above the sea floor of the adjacent Gulf of Maine. A bank, or shoal, is a shallow portion of an ocean that is analogous to a plateau. Georges Bank is part of a large range of shoals that extends from Newfoundland to the edge of the North American continental shelf. Georges Bank itself is larger than the state of New Jersey, and is an extremely important breeding ground for cod, haddo! ck, herring, flounder, lobster, and scallops. Its unique conditions are formed by the mingling of two major Atlantic currents: the cold Labrador current and the warm Gulf stream. The mixing of nutrient-rich and well-oxygenated waters in combination with good light penetration due to shallow depth creates an ideal environment for **plankton** that is a vital food source for young fish.

Known for its abundant fish supply, Georges Bank was heavily fished for centuries. Early fisheries believed the supply to be inexhaustible. The first documented consequence of indiscriminate fishing was in 1850 when, after a concentrated season of overfishing, a dramatic decline in halibut numbers in Georges Bank threatened commerce. The near **extinction** of halibut in this area occurred when ocean fishing was still accomplished using relatively small sailboats and handlines with baited hooks. After World War II, colossal factory-sized fishing ships were created and new large-scale fishing techniques were employed in Georges Bank. Miles of **gill nets** and other efficient methods became standard tools for trolling the bank. Fisheries from the United States, the Soviet Union, Spain, Japan, and Germany collected huge bounties from Georges Bank for decades. Each modern ship could catch as much cod in a single hour as an average boat from the 1600s could collect in an enti! re season. The fishing industry boomed from the 1950s through the 1970s, until it became apparent that even the ocean had limits that could be surpassed.

In 1976, the United States passed the Magnuson Act which established American authority to ban international factory fishing in the Georges Bank area. The intention was to protect and preserve fish stocks for the United States and Canada. Rather than initiate **conservation** strategies for managing the fish populations of Georges Bank, western fisheries free from foreign competition in the area, advanced. The New England Council, created by the Magnuson Act to protect Georges Bank, was effectively controlled by fishing industry interests that did little to address growing concerns about dwindling supplies.

In 1994 the National Marine Fisheries Service estimated a 40% decline in cod stocks in the Georges Bank area that occurred over an alarmingly short four-year period. Survey after survey found that the once abundant bank had been stripped of every prime commercial fish species that once filled its waters. As a result, that same year, fishing was banned in a 9,600 square kilometer area of Georges

Bank. As of 1999, scientists reported that some commercial species were beginning to show signs of a slow increase in numbers, but that cod continued a rapid decline. While the ban on heavy fishing continues, some strictly regulated fishing is permitted in certain areas of Georges Bank. Although the depletion of fish populations in Georges Bank are assumed by some to be temporary, scientists remain cautious about providing assurances of a return to former abundance since recovery from such massive overfishing is not well understood.

Because regions relatively close to land, such as Georges Bank, tend to be more regulated, fishermen have begun to move farther out into unregulated water. Lack of regulations, however, is not the only reason fishermen are going farther offshore. Many populations have been overfished in coastal waters, but fish and shellfish populations have declined in these waters due to near-shore pollution as well. Decreased **water quality** has had an impact on the population numbers and also on the quality of the fish itself, therefore creating a demand for fish and shellfish from distant, presumably cleaner, waters. Being driven farther offshore to make their catches, commercial fishermen may often overfish a population to bring in more revenues to offset their huge debt incurred on their equipment, crew, and ever increasing fuel costs.

A particularly alarming new method of fishing that threatens ocean **fauna** is cyanide fishing. Cyanide fishing is an increasingly popular method of fishing that uses cyanide to temporarily stun fish in exotic areas, like coral reefs. Once stunned, the fish are easily collected, then sold either as aquarium pets or as live fish in restaurants. Live fish sell for much higher prices than frozen fish, and live fish selections in restaurants is a growing trend. One problem with cyanide fishing is that only about half of the fish captured survive for sale, making it a wasteful effort. A second problem is the nonselective **poisoning** of other **wildlife** found in the ecosystems. Coral itself is killed by the cyanide used to flush-out **exotic species** from hiding places for luxury fish markets in Asia. Cyanide fishing constitutes a new threat for overfishing. It is estimated that roughly 65 tons of cyanide are used each year in Philippine coral reefs alone. Cyanide used on one! area spreads and jeopardizes ocean life on a scale that is poorly understood.

Popular trends in cuisine, in addition to live exotic fish selections in restaurants, can effect fishing. During the 1980s, when a New Orleans chef popularized "blackened redfish" and the dish was in demand across the country, the Gulf of Mexico population of "redfish", actually the Red drum, was nearly decimated by overfishing. Because of its unpopularity as a food and game fish, the Red drum was not regulated as are the more important commercial fish and shellfish species of this region. Therefore, when orders for the fish started coming in from across the nation, commercial fishermen began catching them in record numbers. There were cases in which great numbers of dead redfish were washing up on the shores of the Gulf states because fishermen had caught too many to process on their vessels and dumped the excess overboard. In just a couple of years the Red drum population crashed in the Gulf of Mexico, prompting the fish and game officials in all of the Gulf states to halt **commercial fishing** for redfish. (A recovery program, however, is meeting with success.) This problem could have been avoided had the original dish been named "blackened fish" or had the nation's seafood markets and restaurants known that the flavor in "blackened redfish" is in the seasonings and not in the fish itself, thus relying on local fisheries and the redfish of the Gulf of Mexico.

One means of offsetting overfishing by commercial fishing fleets, and reducing fuel use as well, is **aquaculture**, the cultivation and harvesting of fish and shellfish under controlled conditions. With pressures on fish populations from overfishing, increased pollution problems, and a dying industry strapped with higher costs of fuel and equipment, "fish farming" may offer a true alternative to greatly reduced quantities and inferior quality seafood in the future. *See also* Commercial fishing

Overgrazing

Overgrazing is one of the most critical environmental problems facing the western United States. **Rangelands** have been mismanaged for over a hundred years, mainly due to cattle grazing. In addition to consuming vegetation, cattle alter the **ecosystem** of rangeland by tramping, urination, defecation, and trashing. Degradation due to heavy livestock grazing continues to occur in many diverse and fragile ecosystems, including **savanna**, **desert**, meadow, and alpine communities.

Riparian lands, highly vegetated, narrow strips of land bordering rivers or other natural watercourses, make up only two percent of rangelands, but have the most diverse populations of vegetation and **wildlife**. Overgrazing has had a devastating effect on these areas. Cattle eat the seedlings of

young trees, which has led to the elimination of some **species**, and this has reduced the species of birds in these areas and disrupted migratory patterns. Lack of new tree growth in riparian areas has also resulted in the drying up of stream beds and the loss of **habitat** for fish and amphibians. It has contributed to the problem of **soil erosion**, **desertification** and the **greenhouse effect**. Other rangeland ecosystems are facing similar disruption.

The **Bureau of Land Management** (BLM) part of the U. S. Department of the Interior is the largest landholder in the United States. They are responsible for 334 million acres of land which fall under multiple-use mandates. The BLM leases much of this **public land** to individuals for grazing purposes, charging ranchers approximately $1.35 per month to graze one cow and a calf. It has been estimated that the fair market value for such forage is $6.65, and the agency has come under attack for leasing grazing rights at extremely low rates. It has also been criticized for allowing abusive land management practices. Critics claim that those who utilize these public lands try to maximize profits by putting excessive numbers of livestock on the range, and they argue that almost half of the range areas in the United States are in dire need of **conservation**.

Environmentalists argue that it is possible to eliminate overgrazing and manage rangelands in a way that both preserves ecosystems and meets the needs of ranchers. They advocate above all the reduction of herds. They also suggest that cattle should not be allowed to roam at will and should be rotated among various pastures, so that all rangeland areas can receive back-to-back spring and summer rest.

Perhaps the main obstacle in conservation of rangelands is the lack of knowledge regarding their diverse ecosystems. Rangelands are regions where natural revegetation tends to be slow. Artificial attempts to introduce and establish plant growth have been frustrated by the fact that development is a long-term process in these environments as well as by other factors. Knowledge of the dynamics of **competition**, reaction, and stabilization of species is minimal. For over a century, rangers have tried to eliminate sagebrush, planting wheatgrass in its place. The solution has been short-lived because sagebrush usually prevails over wheatgrass in the natural **succession** of plants. To further compound the problem, overgrazing has depleted the perennial grasses that compete with sagebrush, and the plant has become even more prolific. A better understanding of the dynamic relationship between plants, animals, **microorganisms**, soil, and the **climate** is necessary to reestablish rangeland areas. *See also* Agricultural pollution; Agricultural Stabilization and Conservation Services; Agroecology; Feedlot runoff; Feedlots; Land use; Sagebrush Rebellion; Taylor Grazing Act (1934)

Overhunting

Overhunting is any **hunting** activity that has an adverse impact on the total continuing population of a **species**. With the tremendous increase in the human population since the industrial revolution, there has been an ever increasing use and, often, exploitation of many of the world's **natural resources**. The demand for fish and shellfish has exemplified this misuse of natural resources. The amount of hunting pressure that a species can tolerate depends on its productivity, and it may change seasonally and annually because of **drought**, **habitat** alteration, **pollution**, or other **mortality** factors. Hunting which is well-regulated can be sustained, and sportsmen in countries with regulated hunting are quick to point out that they are not responsible for the endangerment or **extinction** of any species.

In unregulated situations, however, overhunting does occur, and it has endangered **wildlife**, even driving some species to extinction. The great auk (*Alca impennis*), a large, flightless, penguin-like bird of the North Atlantic coasts, was so easy to catch that sailors could kill hundreds in a few minutes, and by 1844 they had become extinct. Even the world's most abundant bird, the **passenger pigeon** (*Ectopistes migratorius*), was driven to extinction by overhunting. In the 1800s there were 3 to 5 billion passenger pigeons, about one-fourth of all North American land birds, and enormous flocks of them would darken the sky for days as they flew overhead. One colony in Wisconsin covered 850 square miles (220,149 ha) and included 135 million adult birds. Commercial hunting sent train loads of these birds to markets, including 15 million birds from a single colony in Michigan, and eliminated the species in the early 1900s.

There are several cases where overhunting has nearly exterminated a species. In 1850 there were 60 million American **bison** (*Bison bison*) on the Great Plains of the United States, and within 40 years, overhunting had reduced the wild population to 150 individuals. At the turn of the cen-

tury, snowy egrets (*Leucophoyx thula*) were almost wiped out by hunters who the sold the feathers to be made into fashionable women's hats. Many species of **whales** were also driven to the brink of extinction by whalers.

Many species continue to be overhunted today. Although protected by law, African **rhinoceroses** are endangered by poachers who sell the horns to Yemen and China. In Yemen the horns are used to make dagger handles for wealthy businessmen, and in China they are made into an aphrodisiac and fever-reducing drug which is reportedly useless. Likewise, **elephants** are being slaughtered for their ivory tusks. There were 4.5 million elephants in 1970, and by 1990, only 610,000.

Many large cat species are also threatened by overhunting, because the economic incentive to poach these animals far outweighs the risks of being caught and fined. For example, a Bengal tiger (*Panthera tigris tigris*) fur coat sells for $100,000; an ocelot (*Felis pardalis*) skin sells for $40,000; a **snow leopard** (*Panthera uncia*) skin sells for $14,000; and tiger meat sells for $629 per pound ($286/kg).

Even when appropriate hunting regulations do exist, there are often not enough rangers or **conservation** officers to enforce them. As species become more scarce, the demand increases on the black market, inflating the price, and the economic incentive for **poaching** only becomes greater. Unless appropriate laws are enacted and enforced other species will become extinct from overhunting. *See also* Conservation; Convention on International Trade in Endangered Species of Fauna and Flora; Defenders of Wildlife; Endangered species; Endangered Species Act; Fish and Wildlife Service; IUCN—The World Conservation Union; Wildlife management; Wildlife rehabilitation

Oxidation reduction reactions

An oxidation-reduction or redox reaction is transformation involving electron transfer. It consists of a half reaction in which a substance loses an electron or electrons (oxidation) and another half reaction in which a substance gains an electron or electrons (reduction).

The substance that gains electrons is the **oxidizing agent**, while the substance that gives up electrons is the reducing agent. Adding the two half equations algebraically and eliminating the free electrons gives the complete oxidation-reduction equation. This equation, however, is not an assurance that the reaction will proceed spontaneously as written. One way to know the direction of the reaction is to determine the value of the standard free energy change, ΔG^0, and then to calculate the free energy change, ΔG, for the complete redox reaction. If the resulting value of ΔG is negative, the reaction will proceed spontaneously as written. If ΔG is positive, the reaction can proceed spontaneously in the opposite direction. If ΔG is zero, the reaction is in equilibrium.

Simple redox reactions occur with the direct transfer of electrons from the reducing agent to the oxidizing agent. An example is the reaction between **hydrogen** (H_2) and **chlorine** (Cl_2) to form hydrogen chloride. In this reaction, hydrogen, the reducing agent, donates two electrons to chlorine which is the oxidizing agent. Because it gains electrons, the oxidizing agent changes in valence and becomes more negative or less positive. In the given example, the valence of chlorine changes from 0 to -1. The reducing agent, on the other hand, loses electrons and hence becomes more positive. Thus hydrogen, being the reducing agent in the given example, changes in valences from 0 to +1.

Some common applications of redox reactions in **wastewater** treatment are the **detoxification** of cyanide and the precipitation of chromium. Highly toxic cyanide is converted to nontoxic cyanate and finally to **carbon dioxide** and **nitrogen** gas by the action of strong oxidizing agents, such as chlorine gas or sodium hypochlorite. In removing hexavalent chromium, the objective is to reduce it to trivalent chromium, which is less toxic and can be precipitated out in the form of hydroxide. Hexavalent chromium is reduced by sodium bisulfite or ferrous sulfate in an **acid** medium. Lime can then be applied to precipitate out the trivalent chromium as chromium hydroxide, which collects as a chemical **sludge** upon settling.

In biochemical redox reactions, however, the electrons go through a series of transfers before reaching the terminal acceptor, which is oxygen in **aerobic systems**. Examples of these electron carriers are NAD (nicotinamide adenine dinucleotide), NADP (nicotinamide adenine dinucleotide phosphate), and flavoproteins. In **anaerobic systems**, other

materials such as **nitrates**, sulfates, and **carbon** dioxide may become the electron acceptor, as in the process of **denitrification** in which nitrate (NO_3) is reductively degraded to molecular nitrogen (N_2). In either case, organic or inorganic matter, which serves as food for the **microorganisms**, is the substance oxidized. A simplified stoichiometry of the complete **aerobic** biochemical oxidation of glucose, for example, produces six moles of carbon dioxide and six moles of water with the release of 686 kilocalories per mole. *See also* Corrosion and material degradation; Electron acceptor and donor; Industrial waste treatment; Sewage treatment; Waste management

Oxidizing agent

Any substance that donates oxygen or that gains electrons in a chemical reaction. Perhaps the most common example of an oxidizing agent is the element oxygen itself. When a substance burns, rusts, or decays, that substance combines with oxygen in the air around it. Oxidizing agents can have both beneficial and harmful environmental effects. **Chlorine** gas is used as an oxidizing agent to kill bacteria in the purification of water. **Ozone** damages plant and animal cells by oxidizing them.

Oxygen, dissolved

see **Dissolved oxygen**

Ozonation

The process which takes advantage of the oxidizing properties of **ozone** is known as ozonation. Ozone can be used in a variety of applications including the treatment of drinking water, bottled water, beverages, **wastewater**, industrial wastes, air pollutants, swimming pool water, and cooling tower water. In addition, there are a number of proprietary processes that use ozone, ranging from carpet cleaning to the making of gourmet ice cubes. Ozonation consists of four fundamental tasks: drying and cleaning the oxygen-containing feed-gas; generating ozone in a silent corona **discharge** generator; bringing the ozone into contact with the material being treated; and finally destroying remaining ozone prior to releasing the waste gas to the **atmosphere**. All ozonation processes require ozone generation and contacting, but not all applications require feed-gas preparation and off-gas treatment.

Ozone can be generated by three processes: electrical discharge, **photochemical reaction** with **ultraviolet radiation**, and electrolytic reactions. The latter two methods produce very low concentrations of ozone, limiting their application. Electrical discharge generators are currently the most economical choice for producing large quantities of ozone. Feed-gas must contain oxygen and be free of contaminants such as particles, **hydrocarbons**, and water vapor. For optimum production of ozone, the feed-gas should have a **dew point** of at least -37°F (-40°C) and preferably -73°F (-60°C). Small ozonation systems can use air which is dried before entering the ozone generator. Larger systems may find pure oxygen is economically viable. The temperature of the feed-gas and the generator is one of the most important parameters affecting the production of ozone. High temperatures reduce the concentration of ozone and greatly decrease the life of ozone in the gas phase. The **recycling** of ozone process gases increases the concentration of **nitrogen**, which leads to decreases in ozone production, and, in the presence of water vapor, to the production of corrosive nitric **acid**.

Contacting ozone with the material to be treated is complicated by several factors: ozone is reactive and disappears, so it must be generated at the site where it is used, and the waste ozone in the exhaust gas is toxic. When choosing ozone contacting devices for an aquatic system, two types of reactions must be taken into account. In mass-transfer limited reactions ozone is being consumed faster than it can be transferred to solution. In reaction rate limited reactions ozone is in surplus in solution but the material being oxidized is rate limiting, so that ozone is wasted. Bubble-diffuser systems are commonly used in **water treatment** because they are good compromises for satisfying the need to control both mass-transfer and rate limited reactions. However, in some aquatic applications in-line dissolution and contacting may be the optimum technique for ozonating the water in question.

Exhaust gas or off-gas requires treatment to remove traces of ozone remaining in the gas after contacting. Thermal destruction is one of the most commonly used methods for removing ozone from the waste gas. Other methods for destroying ozone include catalytic destruction, activated **carbon adsorption**, and zeolites. *See also* Industrial waste treatment; Water treatment

Ozone

Ozone is a toxic, colorless gas (but can be blue when in high concentration) with a characteristic acrid odor. A variant of normal oxygen, it had three oxygen atoms per molecule rather than the usual two. Ozone strongly absorbs **ultraviolet radiation** at wavelengths of 220 through 290 nm with peak **absorption** at 260.4 nm. Ozone will also absorb infrared radiation at wavelengths in the range 9-10 μm. Ozone occurs naturally in the ozonosphere (ozone layer), which surrounds the earth, protecting living organisms at the earth's surface from ultraviolet radiation. The ozonosphere is located in the **stratosphere** from 6–31 miles (10–50 km) above the earth's surface, with the highest concentration between 7.5 and 12 miles (12 and 20 km). The concentration of ozone in the ozonosphere is 1 molecule per 100,000 molecules, or if the gas were at standard temperature and pressure, the ozone layer would be 0.12 inch (3 mm) thick. However, the ozone layer absorbs about 90% of incident ultraviolet radiation.

Ozone in the stratosphere results from a chemical equilibrium between oxygen, ozone, and ultraviolet radiation. Ultraviolet radiation is absorbed by oxygen and produces ozone. Simultaneously, ozone absorbs ultraviolet radiation and decomposes to oxygen and other products. **Ozone layer depletion** occurs as a result of complex reactions in the **atmosphere** between organic compounds that react with ozone faster than the ozone is replenished. Compounds of most concern include the byproducts of ultraviolet degradation of **chlorofluorocarbons** (CFCs), **chlorine** and fluorine.

Ozone is also a secondary air pollutant at the surface of the earth as a result of complex chemical reactions between sunshine and primary pollutants, such as **hydrocarbons** and oxides of **nitrogen**. Ozone can also be generated in the presence of oxygen from equipment that gives off intense light, electrical sparks, or creates intense static electricity, such as photocopiers and laser printers. Human olfactory senses are very sensitive to ozone, being able to detect ozone odor at concentrations between 0.02 and 0.05 **parts per million**. Toxic symptoms for humans from exposure to ozone include headaches and drying of the throat and respiratory tracts. Ozone is highly toxic to many plant **species** and destroys or degrades many building materials, such as paint, **rubber**, and some **plastics**. The total losses in the United States each year due to ozone damage to crops, livestock, buildings, natural systems, and human health is estimated to be in the tens of billions of dollars. The threshold limit value (TLV) for **air quality** standards is 0.1 ppm or 0.2 mg O_3 per m^3 of air.

Industrial uses of ozone include chemical manufacturing and air, water, and waste treatment. Industrial quantities of ozone are typically generated from air or pure oxygen by means of silent corona **discharge**. Ozone is used in **water treatment** as a disinfectant to kill pathogenic **microorganisms** or for oxidation of organic and inorganic compounds. Combinations of ozone and **hydrogen** peroxide or ultraviolet radiation in water can generate powerful oxidants useful in breaking down complex synthetic organic compounds. In **wastewater** treatment, ozone can be used to disinfect effluents, or decrease their color and odor. In some industrial applications, ozone can be used to enhance biodegradation of complex organic molecules. Industrial cooling tower treatment with ozone prevents transmission of airborne pathogenic organisms and can reduce odor. *See also* Biodegradable; Ozonation

Ozone layer depletion

Destroying the ozone shield

Ozone, a form of oxygen consisting of three atoms of oxygen instead of two, is considered an air pollutant when found at ground levels and is a major component of **smog**. It is formed by the reaction of various air pollutants in the presence of sunlight. Ozone is also used commercially as a bleaching agent and to purify municipal water supplies. Since ozone is toxic, the gas is harmful to health when generated near the earth's surface. Because of its high rate of breakdown, such ozone never reaches the upper **atmosphere**.

But the ozone that shields the earth from the sun's radiation is found in the **stratosphere**, a layer of the upper atmosphere found 9–30 mi (15–50 km) above ground. This ozone layer is maintained as follows: the action of ultraviolet light breaks O_2 molecules into atoms of elemental oxygen (O). The elemental oxygen then attaches to other O_2 mole-

cules to form O_3. When it absorbs **ultraviolet radiation** that would otherwise reach the earth, ozone is, in turn, broken down into O_2 + O. The elemental oxygen generated then finds another O_2 molecule to become O_3 once again.

In 1974, chemists F. Sherwood Rowland and Mario J. Molina realized that **chlorine** from chlorofluorocarbon (CFC) molecules was capable of breaking down ozone in the stratosphere. In time, evidence began accumulate that the ozone layer was indeed being broken apart by these industrial **chemicals**, and to a lesser extent by **nitrogen** oxide emissions from jet airplanes as well as **hydrogen** chloride emissions from large volcanic eruptions.

When released into the **environment**, CFCs slowly rise into the upper atmosphere, where they are broken apart by solar radiation. This releases chlorine atoms that act as *catalysts*, breaking up molecules of ozone by stripping away one of their oxygen atoms. The chlorine atoms, unaltered by the reaction, are each capable of destroying ozone molecules repeatedly. Without a sufficient quantity of ozone to block its way, ultraviolet radiation from the sun passes through the upper atmosphere and reaches the surface of the earth.

When damage to the ozone layer first became apparent in 1974, **propellants** in **aerosol** spray cans were a major source of CFC emissions, and CFC aerosols were banned in the United States in 1978. However, CFCs have since remained in widespread use in thermal insulation, as cooling agents in refrigerators and air conditioners, as cleaning solvents, and as foaming agents in **plastics**, resulting in continued and accelerating depletion of stratospheric ozone.

The Antarctic ozone hole

The most dramatic evidence of the destruction of the ozone layer has occurred over **Antarctica**, where a massive "hole" in the ozone layer appears each winter and spring, apparently exacerbated by the area's unique and violent climatological conditions. The destruction of ozone molecules begins during the long, completely dark, and extremely cold Antarctic winter, when swirling winds and ice clouds begin to form in the lower stratosphere. This ice reacts with chlorine compounds in the stratosphere (such as hydrogen chloride and chlorine nitrate) that come from the breakdown of CFCs, creating molecules of chlorine.

When spring returns in August and September, a seasonal vortex—a rotating air mass—causes the ozone to mix with certain chemicals in the presence of sunlight. This helps break down the chlorine molecules into chlorine atoms, which, in turn, react with and break up the molecules of ozone. A single chlorine, **bromine**, or nitrogen molecule can break up literally thousands of ozone molecules.

During December, the ozone-depleted air can move out of the Antarctic area, as happened in 1987, when levels of ozone over southern **Australia** and New Zealand sank by 10% over a three week period, causing as much as a 20% increase in ultraviolet radiation reaching the earth. This may have been responsible for a reported increase in skin cancers and damage to some food crops.

The seasonal hole in the ozone layer over Antarctica has been monitored by scientists at the National Aeronautics and Space Administration's (NASA) Goddard Space Flight Center outside Washington, D.C. NASA's NIMBUS-7 satellite first discovered drastically reduced ozone levels over the Southern Hemisphere in 1985, and measurements are also being conducted with instruments on aircraft and balloons. Some of the data that has been gathered is alarming.

In October 1987, ozone levels within the Antarctic ozone hole were found to be 45% below normal, and similar reductions occurred in October 1989. A 1988 study revealed that since 1969, ozone levels had declined by 2% worldwide, and by as much as 3% or more over highly populated areas of North America, Europe, South America, Australia and New Zealand.

In September 1992, the NIMBUS-7 satellite found that the depleted ozone area over the southern polar region had grown 15% from the previous year, to a size three times bigger than the area of the United States, and was 80% thinner than usual. The ozone hole over Antarctica was measured at approximately 8.9 million mi^2 (23 million km^2), as compared to its usual size of 6.5 million mi^2 (17 km^2). The contiguous 48 states is, by comparison, about 3 million mi^2 (7.8 million km^2), and all of North America covers 9.4 million mi^2 (24.3 million km^2). Researchers attributed the increased thinning not only to industrial chemicals but also to the 1991 volcanic eruptions of **Mount Pinatubo** in the Philippines and Mount Hudson in Chile, which emitted large amounts of **sulfur dioxide** into the atmosphere.

Dangers Of ultraviolet radiation

The major consequence of the thinning of the ozone layer is the penetration of more solar radiation, especially Ultraviolet-B (UV-B) rays, the most dangerous type, which can be extremely damaging to plants, **wildlife**, and human health. Because UV-B can penetrate the ocean's surface, it is potentially harmful to marine life forms and indeed to the entire chain of life in the seas as well.

UV-B can kill and affect the reproduction of fish, larvae, and other plants and animals, especially those found in shallow waters, including **phytoplankton**, which forms the basis of the oceanic **food chain/web**. The National Science Foundation reported in February 1992 that its research ship, on a six week Antarctic cruise, found that the production of phytoplankton decreases at least 6–12% during the period of greatest ozone layer depletion, and that the destructive effects of UV radiation could extend to depths of 90 ft (27 m).

A decrease in phytoplankton would affect all other creatures higher on the food chain and dependent on them,

including **zooplankton**, microscopic ocean creatures that feed on phytoplankton and are also an essential part of the ocean food chain. And marine phytoplankton are the main food source for **krill**, tiny Antarctic shrimp that are the major food source for fish, squid, penguins, **seals**, **whales**, and other creatures in the Southern Hemisphere.

Moreover, phytoplankton are responsible for absorbing, through **photosynthesis**, great amounts of **carbon dioxide** (CO_2) and releasing oxygen. It is not known how a depletion of phytoplankton would affect the planet's supply of life-giving oxygen, but more CO_2 in the atmosphere would exacerbate the critical problem of global warming, the so-called **greenhouse effect**.

There are numerous reports, largely unconfirmed, of animals in the southern polar region being harmed by ultraviolet radiation. Rumors abound in Chile, for example, of pets, livestock, sheep, rabbits, and other wildlife getting cataracts, suffering reproductive irregularities, or even being blinded by solar radiation. Many residents of Chile and Antarctica believe these stories, and wear sunglasses, protective clothing, and sun-blocking lotion in the summer, or even stay indoors much of the day when the sun is out. If the ozone layer's thinning continues to spread, the lifestyles of people across the globe could be similarly disrupted for generations to come.

Particularly frightening have been incidents reported to have taken place in Punta Arenas, Chile's southernmost city, at the tip of Patagonia. After several days of record low levels of ozone were recorded in October 1992, people reported severe burns from short exposure to sunlight. Sheep and cattle became blind, and some starved because they could not find food. Trees wilted and died, and melanoma-type skin cancers seem to have increased dramatically. Similar stories have been reported from other areas of the southern hemisphere. And malignant melanoma, once a rare disorder, is now the fastest rising **cancer** in the world.

Ozone thinning spreads

Indeed, ozone layer depletion is spreading at an alarming rate. In the 1980s, scientists discovered that an ozone hole was also appearing over the Arctic region in the late winter months, and concern was expressed that similar thinning might begin to occur over, and threaten, heavily populated areas of the globe. These fears were confirmed in April 1991, when the **Environmental Protection Agency** (EPA) announced that satellite measurements had recorded an ominous decrease in atmospheric ozone, amounting to an average of 5% over the mid-latitudes (including the United States), almost double the loss previously thought to be occurring.

The data showed that ozone levels measured in the late fall, winter, and early spring over large areas of the United States, Europe, and the mid-latitudes of the Northern and Southern Hemisphere had dropped by 4–6% over the last decade—twice the amount estimated in earlier years. The greatest area of ozone thinning in the United States was found north of a line stretching from Philadelphia to Denver to Reno, Nevada. One of the most alarming aspects of the new findings was that the ozone depletion was continuing into April and May, a time when people spend more time outside, and crops are beginning to sprout, making both more vulnerable to ultraviolet radiation.

The new findings led the EPA to project that over the next 50 years, thinning of the ozone layer could cause Americans to suffer some 12 million cases of skin cancer, 200,000 of which would be fatal. Several years earlier, the agency had calculated that over the next century, there could be an additional 155 million cases of skin cancers and 3.2 million deaths if the ozone layer continued to thin at the then current rate. Another EPA projection made in the 1980s was that the increase in radiation could cause Americans to suffer 40 million cases of skin cancer and 800,000 deaths in the following 88 years, plus some 12 million eye cataracts.

No one can say how accurate such varying projections will turn out to be, but evidence of ozone layer thinning is well-documented. In October 1991, additional data of spreading ozone layer destruction were made public. Dr. Robert Watson, a NASA scientist who co-chairs an 80-member panel of scientists from 80 countries, called the situation "extremely serious," saying that "we now see a significant decrease of ozone both in the Northern and Southern Hemispheres, not only in winter but in spring and summer, the time when people sunbathe, putting them at risk for skin cancer, and the time when we grow crops."

In February 1992, a team of NASA scientists announced that they had found record high levels of ozone-depleting chlorine over the Northern Hemisphere. This could, in turn, lead to an ozone "hole" similar to the one that appears over Antarctica developing over populated areas of the United States, Canada, and England. The areas over which increased levels of **chlorine monoxide** were found extended as far south as New England, France, Britain, and Scandinavia.

Action to protect The ozone layer

As evidence of the critical threats posed by ozone layer depletion has increased, the world community has begun to take steps to address the problem. In 1987, the United States and 22 other nations signed the Montreal Protocol, agreeing, by the year 2000, to cut CFC production in half, and to phase out two ozone-destroying gases, Halon 1301 and Halon 1211. **Halons** are man-made bromine compounds used mainly in fire extinguishers, and can destroy ozone at a rate 10 to 40 times more rapidly than CFCs. Fortunately, these

restrictions appear to already be having an impact. In 1992, it was found that the rate at which these two Halon gases were accumulating in the atmosphere had fallen significantly since 1987. The rate of increase of levels of Halon 1301 was about 8% a year from 1989 to 1992, about half of the average annual rate of growth over previous years. Similarly, Halon 1211 was increasing at only 3% annually, much less than the previous growth of 15% a year.

Since the Montreal Protocol, other international treaties have been signed limiting the production and use of ozone-destroying chemicals. When alarming new evidence on the destruction of stratospheric ozone became available in 1988, the world's industrialized nations convened a series of conferences to plan remedial action. In March 1989, the 12-member European Economic Community (EEC) announced plans to end the use of CFCs by the turn of the century, and the United States agreed to join in the ban. A week later, 123 nations met in London to discuss ways to speed the CFC phase-out. The industrial nations agreed to cut their own domestic CFC production in half, while continuing to allow exports of CFCs, in order to accommodate **third world** nations.

Ironically, the large industrial nations, which have created the CFC problem, are now much more willing to take effective action to ban the compounds than are many developing nations, such as India and China. The latter nations resist restrictions on CFCs on the grounds that the chemicals are necessary for their own economic development.

After the meeting in London, leaders and representatives from 24 countries met in an environmental summit at The Hague, and agreed that the United Nations' authority to protect the world's ozone layer should be strengthened.

In May 1989, members of the EEC and 81 other nations that had signed the 1987 Montreal Protocol decided at a meeting in Helsinki to try to achieve a total phase-out of CFCs by the year 2000, as well as phase-outs as soon as possible of other ozone-damaging chemicals like **carbon** tetrachloride, halons, and methyl chloroform. In London in June 1990, most of the Montreal Protocol's signatory nations formally adopted a deadline of the year 2000 for industrial nations to phase out the major ozone-destroying chemicals, with 2010 being the goal for developing countries.

Finally, in November 1992, 87 nations meeting in Copenhagen decided to strengthen the action agreed to under the Montreal Protocol and move up the phase-out deadline from 2000 to January 1, 1996, for CFCs, and to January 1, 1994, for halons. A timetable was also agreed to for eliminating **hydrochlorofluorocarbons** (HCFCs) by the year 2030. HCFCs are being used as substitutes for CFCs even though they also deplete ozone, albeit on a far lesser scale than CFCs. The conference failed to ban the production of the **pesticide** methyl bromide, which may account for 15% of ozone depletion by the year 2000, but did freeze production at 1991 levels.

Environmentalists were disappointed that stronger action was not taken to protect the ozone layer. But Environmental Protection Agency (EPA) Administrator William K. Reilly, who headed the U.S. delegation, estimated that the reductions agreed to could, by the year 2075, prevent a million cases of cancer and 20,000 deaths.

Although the restrictions apply to developed nations, which produce most of the ozone-damaging chemicals, it was also agreed to consider moving up a phase-out of such compounds by developing nations from 2010 to 1995. A month after the Copenhagen conference, the nations of the European Community agreed to push bans on the use of CFCs and carbon tetrachloride to 1995 and to cut CFC emissions by 85% by the end of 1993.

The private sector has also taken action to reduce CFC production. The world's largest manufacturer of the chemicals, DuPont Chemical Company, announced in 1988 that it was working on a variety of substitutes for CFCs, would phase out production of them by 1996, and would partially replace them with HCFCs. Environmentalists charge that DuPont has been moving too slowly to eliminate production of these chemicals.

There are many ways that individuals can help reduce the release of CFCs into the atmosphere, mainly by avoiding products that contain or are made from CFCs, and by **recycling** CFCs whenever possible. Although CFCs have not generally been used in spray cans in the United States since 1978, they are still used in many consumer and industrial products, such as styrofoam. Other products manufactured using CFCs include solvents and cleaning liquids used on electrical equipment, **polystyrene** foam products, and fire extinguishers that use halons.

Refrigerants in cars and home air conditioning units contain CFCs and must be poured into closed containers to be cleaned or recycled, or they will evaporate into the atmosphere. Using foam insulation to seal homes also releases CFCs. Many alternatives to foam insulation exist, such as cellulose fiber, gypsum, fiberboard, and fiberglass.

Unfortunately, whatever steps are taken in the next few years, the problem of ozone layer depletion will continue even after the release of ozone-destroying chemicals is limited or halted. It takes six to eight years for some of these compounds to reach the upper atmosphere, and once there, they will destroy ozone for another 20–25 years. Thus, even if all emissions of destructive chemicals were stopped, compounds already released would continue to damage the ozone layer for another quarter century.

Understanding ozone depletion

As detailed collection of data about interactions in the stratosphere progresses, the observational support for the ozone depletion theory continues to grow more compelling. Yet atmospheric scientists are beginning to realize that their understanding of the upper atmosphere is still quite crude. While certain key reactions which maintain and destroy ozone are theoretically and observationally supported, scientists will have to comprehend the interaction of dozens, if not hundreds, of reactions between natural and artificial **species** of hydrogen, nitrogen, bromine, chlorine and oxygen before a complete picture of ozone-layer dynamics emerges. The recent eruption of **Mount Pinatubo**, for example, made scientists aware that *heterogenous processes*—those reactions which require cloud surfaces to take place—may play a far greater role in causing ozone depletion than originally believed. Such reactions had previously been observed taking place only at the earth's poles, where stratospheric clouds form during the long winter darkness, but it is now thought that sulfur aerosols ejected by Pinatubo may be serving as a catalyst to speed ozone depletion at nonpolar latitudes.

Ironically, ozone-depleting reactions are best understood around the thinly inhabited polar regions, where stable and isolated conditions over the winter allow scientists to understand stratospheric changes most easily. In contrast, at the temperate latitudes where constantly moving air masses undergo no seasonal isolation, it is difficult to determine whether a fluctuation in a given chemical's density is a result of local reactions or atmospheric turbulence. In 1995, the Nobel Prize for Chemistry was awarded to F. Sherwood Roland, Mario Molina and Paul Crutzen for their work on the formation and destruction of the ozone layer. It is hoped that increasingly detailed measurements using a new generation of equipment (such as NASA's *Perseus* remote-control aircraft) will begin to shed more light on the processes occurring away from the poles. Joe Waters of NASA's Jet Propulsion Laboratory summarizes the urgent task: "We must be able to lay out the catalytic cycles that are destroying ozone at all altitudes all over the globe—from its production region in the tropics to the higher latitudes and the polar regions." *See also* Photochemical reaction

Paleoecology/paleolimnology

Paleoecology, the scientific study of ancient environments and the interrelationships of their plants and animals, and paleolimnology, the scientific study of evidence of ancient inland waterways, including lakes, ponds, freshwater marshes, and streams, were both established at the end of the nineteenth century. The roots of both disciplines can be traced to early nineteenth-century botanical and chemical studies, and later, geological studies of the consolidated sediments of ancient lake beds, in which their organisms and environments were examined in relationship to both the lakes and the surrounding uplands.

By the early 1920s, limnologists began to collect **sediment** cores from lakes and to interpret stratigraphic data from plant and animal fossils as a record of a lake's history. This provided clues to how lakes had changed over time as a result of either natural events or human activities. Data collected from lakes and **wetlands** provide baselines to compare the impacts of a activities such as land clearance, **drainage**, **water pollution**, and **air pollution**. They can also be used to assess the rate of recovery from the activities once they have ended.

Lake and wetland sediments contain detailed archeological records of how the overlying ecosystems have been affected over time. It is in many ways equivalent to archeological reconstruction of past civilizations by examining their stratified remains. Lake sediments and wetland peat deposits form a selective trap for a variety of plant and animal remains and elements such as **carbon**, **phosphorus**, sulfur, iron, and manganese that are stored at varying concentrations depending on the activities that were occurring at the time the sediment layer was formed. Changes in this profile record not only the history of the lake or peatland but also what happened in the surrounding **watershed**. Initially, limnologists collected core samples from lakes and interpreted them on the basis of plant and animal fossils. The limnologists observed that in some lakes there were thin laminated sediments. These were shown to result from an annual deposition cycle which involves summer deposition of calcium carbonate and deposition of organic matter during the rest of the year. These alternating light and dark layers represent a yearly cycle. Using these bands, or laminae, scientists can count back in time and date individual strata of sediment cores.

Studying plant and animal microfossil remains (such as pollen, diatom shells, and remains of **zooplankton** bodies) in the sediment cores and knowing the environments in which these organisms occur today allow a limnologist to reconstruct historical conditions in a lake as well as in its drainage basin. Such wetland studies were limited, however, until the development of **radioisotope** dating methods in the 1950s and 1960s. Today radioisotopes such as carbon-14 and lead-210 can be used to date the time a sediment was deposited.

Other methods limnologists use include the pollen, which indicates what types of land vegetation were present. They also examine plant and animal fossil remains, including cell fragments and molecules such as plant pigments, all of which provide clues about vegetation and aquatic life. Limnologists also search for organic pollutants and certain trace elements, whose presence indicates the result of human activities.

Analysis of the layers in sediment cores from lakes and wetlands has provided information about regional variations in past climatic conditions and watershed vegetation patterns which indicates the causes of environmental change. Studies on recently deposited lake sediments have provided evidence for the timing and causes of lake **pollution**, including the effects of excess nutrients on lake **ecology** and information about atmospheric transport of various pollutants.

These techniques have also been applied to address basic plant ecology questions regarding plant **succession**, on which there are two major schools of thought. The first

is the community concept which has three basic attributes: vegetation occurs in recognizable and characteristic communities; community change through time occurs because of the vegetation; and the changes occur in a sequence that leads to a mature stable climax **ecosystem**. The community explanation can be contrasted with the continuum concept. Here, the distribution of vegetation is determined by the **environment**. Since each plant **species** adapts differently, no two occupy the exact same location. Additionally, the observed replacement sequence is influenced by the chance occurrence of viable seeds that allows a certain plant to grow on the site. This results in a continuum of overlapping sets of species. In this scenario although ecosystems change, it is not directed toward a particular climax community.

One of the areas where these two concepts directly collide is in the study of wetlands and **peatlands**. The classical community view of succession is that wetlands are a transitional stage in the progression from shallow lake to terrestrial forested climax community. This view requires that lakes gradually fill in as organic material from dying plants accumulates and minerals are carried down from upslope into the water. At first change is slow, but it accelerates when the lake becomes shallow enough to support rooted aquatic plants. When the water becomes even more shallow, it supports the development of a peat mat, allowing trees and shrubs to grow which further modifies the site by not only adding organic matter but also by drying the site through **evapotranspiration**. According to the community version, in the final stages a climax forest occupies the site. This sequence implies that most of the change is caused by plants and not external environmental changes.

Paleoecological analyses of peat beds have provided information refuting the validity of the community concept's explanation. Fossil records including analysis of pollen in northern peat lands provide two generalizations: in some sites the present vegetation has existed for several thousand years and climatic change and **glaciation** had a large impact on plant species and distribution. Generally, bogs expanded during warm, wet periods and contracted during cool, drier periods although the influence of local topographic and drainage conditions often mask climatic shifts.

While this evidence supports the continuum assumptions that other environmental factors overwhelm the vegetation effects, there is evidence within the bogs that says that vegetation can have a large impact on the character of the landscape. In particular, this is evidenced by the patterned landscape of these peatlands as the water flow is changed due to the vegetation. It seems that in the wetlands or bogs themselves there can be changes in vegetation that occur over time as a result of succession. However, these changes do not necessarily point toward a terrestrial climax. In fact, pollen profiles indicate that a bog, not some type of terrestrial forest, is the endpoint. These studies confirmed conclusions from a classical study on the Lake Aggassiz Plain (Minnesota and south-central Canada) that indicates most of the peatlands developed during a moist **climate** about 4,000 years ago when surface water levels rose about 12 ft (4 m). This implies that while there may be changes within the peatlands, they are stable, so the central concepts of succession in this case are not supported.

Examples of the findings and results of some significant types of paleolimnological studies show how they are useful in evaluating changes and as indicators of potential problems due to human activities. The Red Lake peatland in northwestern Minnesota has been used as a study site to document the occurrence of **acid rain** and global warming. Based on past changes in the type of vegetation and changes in **pH**, future impacts on the bog surface can be evaluated. If **acid deposition** were to lower the pH of the bog significantly, different types of mosses would be evident. Likewise, if global warming were to lower the water tables' moss types, characteristics of drier conditions would occur.

Using sediment cores from lakes and observing the changes in **flora**, **fauna**, and chemistry allows the evaluation of impacts of human settlement on lakes in the upper Midwest of the United States. A lake studied in northern Minnesota on the iron range shows these changes. There was a distinct increase in hematite (iron) grains in the sediments as mining began and a decrease as it declined. Settlement was also marked by a rise in the concentration or ragweed pollen which reflects the replacement of the forests with agricultural fields. There were also changes in the type of diatom shells reflecting the **nutrient** enrichment of the lake due to the **discharge** of sewage directly to the lake. By analyzing the pH preferences of individual species of diatoms and algae the past pH conditions in a lake can be determined. Using the results of these studies it has been demonstrated that lakes in the **Adirondack Mountains** were not naturally acidic. Current monitoring suggests that these lakes that were acidified due to **acid** rain have not yet responded reductions in the amount of sulfate deposition.

Parasites

Organisms that live in or upon the body of a host organism and are metabolically dependent on the host for completion of their life cycle. Parasites may be plants, animals, viruses, bacteria, or **fungi**. Parasites feed either on their host directly or upon its surplus fluids. Some parasites, known as endoparasites, live inside their host, while ectoparasites live on the outside of their host. Organisms in which parasites reach maturity are called definitive hosts, and hosts harboring parasite stages are called intermediate hosts. Organisms which spread parasite stages between hosts are known as vectors. Full-time, or obligatory, parasites have an absolute dependence on their hosts. Examples of this type are viruses, which can only live and multiply inside living cells, and tapeworms, which can only live and multiply inside other **species**. Part-time, or facultative, parasites, such as wood ticks, have parasitic and free-living stages in their life cycle and are only temporary residents of their hosts.

The effects of parasites on their hosts depend on the health of the host, as well as the severity of the infestation. In diseased, old, or poorly-fed individuals, parasite infestations can be fatal, but parasites do not typically kill their hosts, though they can slow growth and cause weight loss. Some plant parasites do kill their host and then live on its decomposing remains, and certain species of hymenopteran insect are parasitoids, whose larva feeds within the living body of the host, eventually killing it. Some parasites, such as *Sacculina*, castrate their host by infecting its reproductive organs. Cuckoos are brood parasites, and they lay their eggs in the nest of another bird species, evicting the eggs that were there and leaving the young cuckoos to be raised by the parents of the host species.

In **community ecology**, parasites are often grouped together with predators, since both feed directly upon other organisms, either harming them or killing them. Ecologically, small disease-causing organisms (viruses, bacteria, protozoans) are regarded as microparasites, while larger parasites (flatworms, roundworms, lice, fleas, ticks, rusts, mistletoe) are macroparasites. Together with predators and diseases, parasites are one of the natural components of environmental **resistance** which serves to limit **population growth**. Microparasites that are transmitted directly between infected hosts, such as rabies or distemper, target herd animals with a high host density and can significantly reduce population levels. Macroparasites that employ one or more intermediate hosts, such as flukes, tapeworms, or roundworms, have highly effective transmission stages but usually have only a limited effect on the population of the host.

Parasites can play a larger role in altered ecosystems. In the eastern United States parasitic infections have held populations of cottontail rabbits well below the **carrying capacity** of the **habitat**. Parasitic insects have been used to control populations of the olive scale insect, a serious **pest** of olive trees in California. Accidentally introduced parasites have negatively impacted populations of commercial species by altering the balance of the **ecosystem**. For example, a protozoan parasite infecting California oysters was introduced to French oyster beds, wiping out the native European oysters and seriously damaging **commercial fishing** there. *See also* Population biology; Predator-prey interactions

Pareto optimality (Maximum social welfare)

Usually, one thinks of efficiency as not being wasteful or getting the most out of the resources one has available. Economists offer the Pareto optimum—"a situation where no one can be better off without making someone worse off." Derived from the work of the Italian economist and sociologist Vilfredo Pareto, whose late nineteenth-century writings on political economy inspired much thinking about what made an economy efficient, Pareto optimality has come

to mean making at least one person better off without making anyone else worse off. For an economy, it means that the allocation of resources is optimal if no other allocation exists wherein a person is better off and everyone is at least as well off. Economic theory holds that these conditions are met if consumers maximize utility, producers maximize profits, competition prevails, and information is adequate for the making of rational decisions. A free market unconstrained by government involvement, it is assumed, will achieve Pareto optimality by an invisible hand, that is, automatically, provided that production and consumption decisions do not entail substantial environmental disamenities. Imperfect market conditions, which include environmental disamenities on a large scale, challenge the assumptions of Pareto optimality and call for remedial measures such as **pollution** taxes or **emission** rights to restore market efficiency. *See also* Externalities

Parrots and parakeets

These intelligent, brightly colored, affectionate birds are found mainly in warm, tropical regions and have long been popular as pets, in large part because many of them can learn to talk. But capture of wild parrots for the **pet trade**, along with the destruction of forests, have decimated populations of these birds, and many **species** are now threatened with **extinction**.

About half of the approximately 315 species of parrots in the world are native to Central and South America. Members of the parrot order (Psittaciformes) include the macaws of Central and South America, which are the largest parrots, with bright feathers; cockatoos of **Australia** with white feathers and crests on their heads; lorikeets of Australia with orange-red bills and brightly-colored feathers; cockatiels, which are small, long-tailed, crested parrots also from Australia; and parakeets, which are small, natural acrobats, usually with green feathers. Parakeets include lovebirds from Africa and budgies from Australia. Budgies are the most common type of pet parakeet, and they can be trained to say many words. Most parakeets sold as pets are bred for that purpose, thus their trade does not usually threaten wild populations.

Part of the attraction of parrots is their high intelligence, but this can make them unsuitable pets. The birds are often loud and they demand a great deal of attention, and many people who buy parrots give them up because of the frustrations of owning one of these complex birds. In addition, parrots often carry a disease called *psittacosis* which can be transmitted to humans and commercially raised poultry. For this reason, parrots must be examined by officials from the **U.S. Department of Agriculture** (USDA) before entering the United States, and hundreds of thousands of parrots have been destroyed to prevent the spread of psittacosis.

The large scale capture of parrots for the legal and illegal pet trade has been a major factor in the depletion of these beautiful birds. The world trade in wild birds has been estimated at over seven million annually, and the United States is the world's largest consumer of exotic birds. Over 1.4 million wild birds were imported into this country during 1988–1990, and half of these were parrots and other birds supposedly protected under the **Convention on International Trade in Endangered Species of Wild Fauna and Flora** (CITES). The **mortality** rate for birds transported in international trade is massive. For every wild bird that makes it to the pet store, at least five may have died on the way, and USDA **statistics** show that 79,192 birds perished in transit to the United States from 1985 to 1990, and 258,451 died while in quarantine or because they were refused entry due to Newcastle disease. In 1991 one airline shipment alone included 10,000 dead birds. Moreover, the shock of capture and caging the birds before shipment may cause even greater mortality rates.

As a species becomes rare or endangered, it often becomes more valuable and sought-after, and some parrots have been sold for $10,000 or more. In October 1992, shortly before being named Secretary of the Interior, former Arizona governor Bruce Babbitt addressed the annual meeting of the **Humane Society of the United States**. Expressing dismay at "the looming extinction of tropical parrots and macaws in South America," he described their exploitation in the following terms: "These birds are captured for buyers in the United States who will pay up to $30,000 for a hyacinth macaw. You can stand on docks outside Manaus, Brazil, and other towns in the Amazon and see confiscated crates with blue and yellow macaws, their feet taped, their beaks wired, stacked up like cordwood in boxes. They have a fatality rate of 50% by the time they're smuggled into Miami."

Some progress has been made in restricting the international trade in parrots. By the end of 1992 over 100 airlines had agreed to forbid the carrying of wild birds. The Wild Bird Conservation Act, signed into law on October 27, 1992, bans trade immediately for several severely exploited bird species and, within a year of passage, outlaws commerce in all parrots and other birds protected under CITES. The act requires exploiters to prove that a species can withstand removal from the wild. This has greatly reduced the number of birds imported into the United States. Conservation groups, such as the Humane Society of the United States and the **Animal Welfare Institute**, have worked for years to secure passage of this legislation.

Nevertheless, the persistence of smuggling as well as the legal trade in some species of these birds will continue

to threaten wild populations. This is especially true when the trees in which parrots nest are cut down to provide collectors access to chicks in the nest. As of 2002, 16 parrot species, 10 parakeet species, and three macaw species were listed as endangered by the **U.S. Department of the Interior**, and all species of parrots, parakeets, macaws, lories, and cockatoos are listed in the most endangered categories of CITES. IUCN—The World Conservation Union—includes 69 members of the parrot order in its 2000 list of threatened animals.

Nine parrots are listed as extinct by IUCN. One is the beautiful orange, yellow, and green Carolina parakeet (*Conuropsis carolinensis*) once ranged in large numbers from Florida to New York and Illinois, but the demand for its feathers by the millinery trade was so great that the species was hunted into extinction between 1904 and 1920. Conservationists fear that several other species of the parrot family may soon join the Carolina parakeet on the list of extinct birds.

Particulate

An adjective describing anything that consists of, or relates to, particles. The term was formerly used in laboratory slang to stand for "particulate matter," but this use has nearly disappeared since its repudiation by the **Environmental Protection Agency** (EPA). The term particulate matter, which often means the particle content of a given volume of air, is used as a more inclusive variant of "particles."

Typical atmospheric particulate matter may comprise three populations of particles according to size. The smallest of these is found only near sources, since the particles rapidly aggregate to larger sizes. The upper size limit for these particles is near 0.1 micrometer (1 micrometer = 1 μm = 0.001 mm). Number concentrations can be quite high. This population is referred to as the nuclei mode of particles. The next larger size class, which begins at a diameter of about 0.1 μm and extends to about 2.0 μm, is called the accumulation mode, since once in the air it tends to remain for days; number concentrations have become low enough that **agglomeration** is slow, and settling velocities are very small. The sum of the nuclei mode and the accumulation mode is called the fine particles. These are characteristically formed by condensation from the gas phase, or by agglomeration of particles formed from the gas phase. The final particle population in air is called the coarse mode, or simply the coarse particles. These are of any size larger than about 2 μm (about 1/10,000 inch), and are formed by mechanical grinding of larger masses of matter. Coarse particles are usually particles of local **soil** or rocks.

Partnership for Pollution Prevention

The Partnership for **Pollution** Prevention (Ppp) is an international cooperative effort to ensure the environmental sustainability of the Western Hemisphere. Pollution prevention requires the efficient utilization of raw materials and energy, as well as modifications in products and manufacturing processes to minimize environmental impact. The Ppp promotes technical and financial cooperation and information exchange among nations. It also promotes the adoption of strict, internationally compatible environmental laws and regulations and the implementation of international environmental agreements. The Ppp works toward improving technologies for environmental protection and increasing public awareness and participation in environmental issues, particularly among indigenous groups and other affected communities. Finally, the Ppp encourages the inclusion of sustainability objectives in other developmental and national policies.

The Ppp is Action Initiative 23 of the Plan of Action developed at the First Summit of the Americas, held in Miami, Florida, in 1994. It is based on the policies formulated at the 1992 United Nations Conference on Environment and Development and the 1994 Global Conference on the **Sustainable Development** of Small Island Developing States. The initial Ppp priorities were formulated at a meeting in San Juan, Puerto Rico, in November 1995. The meeting also addressed issues of financing, public-private partnerships, new legislation, compliance and enforcement, and public participation. Sponsored by the Organization of American States (OAS), the U.S. **Environmental Protection Agency** (EPA), and the Pan American Health Organization (PAHO), this meeting included representatives from 20 countries, as well as members of international organizations, non-governmental organizations, and development banks.

The initial Ppp priorities are health and environmental problems stemming from **lead** contamination and the misuse of pesticides. The Ppp also addresses problems of waste, air and **water quality**, **marine pollution**, and urbanization.

Under the Ppp, 10 nations have made formal political commitments in the areas of health and the environment. Furthermore, under the Ppp, the environmental policies of the **North American Free Trade Agreement** (NAFTA) are being integrated with its trade and economic policies, and NAFTA is confronting issues of **pesticide** registration and chemical **pollution control**.

An OAS meeting in 1996 that included the Inter-American Development Bank, the **World Bank**, the PAHO, the EPA, and the United States Agency for International Development (USAID) formed a task force for Ppp implementation. In October 1997 the task force merged with a similar task force from the 1996 Santa Cruz (Bolivia) Summit on Sustainable Development. This new task force established a number of working groups to address cleaner production, innovative financing for sustainable development, improved access to drinking water, and the networking of environmental experts. The working group on energy infrastructure has obtained funding for a gas pipeline being constructed between Santa Cruz and São Paolo, Brazil. The working group for sustainable cities and communities initiates projects to strengthen local governments, promote local involvement in planning, and improve access to capital and to low-income housing.

The Ppp working group to phase out leaded **gasoline** has served as a model for other working groups. The EPA, PAHO, and the World Health Organization (WHO) have held lead phase-out training workshops. The World Bank works with individual countries to finance refinery upgrades and conversions. As a result of these efforts, a number of nations have banned the sale of leaded gasoline. Leaded gasoline is expected to be eliminated from the Western Hemisphere by 2007. The World Bank, USAID, and the EPA also have developed a lead-monitoring program for children and adults in Latin America and the Caribbean.

Under the auspices of the Ppp, the Cleaner Production Conference of the Americas was held in São Paulo in 1998. It established the Cleaner Production Roundtable of the Americas, a formal network of cleaner production practitioners who share ideas and promote the benefits of cleaner production for sustainable development. The conference also set up a communications network and identified priority needs for cleaner production and pollution controls.

Under the Ppp, the USAID's Regional Environmental Project for Central America, in collaboration with the EPA and the Central American Commission on Environment and Development, has established regional pollution prevention networks to address **solid waste** and wastewater management and the safe use of pesticides. Wastewater and air-contamination regulations, municipal pollution prevention and environmental action plans, and a training network in **environmental law** have been established in Central American countries. As part of the Ppp, the USAID has carried out projects for pollution prevention, clean industrial technologies, and coastal and marine management throughout Latin America and the Caribbean.

Parts per billion

A means of expressing minute concentrations, often of an element, compound, or particle that contaminates **soil**, water, air, or blood. The expression may be on either a mass or a volume basis, or a combination of the two, such as micrograms of a chemical per kilogram of soil, or micrograms of chemical per liter of water. In the United States, one billion equals $1x10^9$. **Dioxin**, a contaminant associated with the **herbicide 2,4,5-T** and implicated in the formation of **birth defects**, can cause concern at concentrations measured in ppb.

Parts per million

A means of expressing small concentrations, usually of an element, compound, contaminant, or particle in water or a mixed medium such as **soil** and normally on a mass basis. Units that are equivalent to ppm include micrograms per gram, milligrams per kilogram, and milligrams per liter.

One ppm times 10,000 equals one part per hundred or one percent. The **nutrient phosphorus** and the contaminant **lead** found in soil are commonly measured in ppm.

Parts per trillion

A means of expressing extremely minute concentrations of substances in water or air. In the United States, the concentration is the number of units of the substance found in $1x10^{12}$ units of water or air; an equivalent unit is nanograms per kilogram. Detection of concentrations this low, which was not possible until the late twentieth century, is limited to only a few types of chemical compounds. For example, one gram of sulfur hexafluoride, used as a tracer in studies of ocean mixing, can be detected in a cubic kilometer of sea water, a concentration of 1,000 parts per trillion.

Passenger pigeon

The passenger pigeon (*Ectopistes migratorius*), perhaps the world's most abundant bird **species** at one time, became extinct due directly to human activity. In the mid-1800s passenger pigeons travelled in flocks of astounding numbers. Alexander Wilson, the father of American ornithology, noted a flock he estimated to contain two billion birds. The artist and naturalist John James Audubon once observed a flock over a three-day period and estimated the birds were flying overhead at a rate of 300 million per hour.

The species became extinct within a span of 50 years, several factors having led to its rapid demise. The passenger pigeon was considered an agricultural **pest**, thus providing ample reason to kill large numbers of the birds. It was also in demand as food, largely due to the fact that nesting flocks were easily accessible. Young squabs were easy prey for hunters who knocked them from their nests or forced them out by setting fires below them. Adults were also killed in huge numbers. They were baited with alcohol-soaked grain or with captive pigeons set up as decoys, then trapped and shot. A common practice of the day was to use the live pigeons as targets in shooting galleries. In 1878, near Petoskey, Michigan, a professional market hunter earned $60,000 by killing over three million passenger pigeons near their nesting grounds. Once killed, many of the birds were packed in barrels and shipped to cities where they were sold in markets and restaurants. The demand was particularly high on the East Coast where forest clearing and **hunting** had already eradicated the species from the area.

By the 1880s commercial hunting of passenger pigeons was no longer profitable, because the population had been depleted to only several thousand birds. Michigan provided their last stronghold, but that population became extinct in 1889. The remaining small flocks of birds were so spread out and isolated that their numbers were too low to be maintained. The disruption of the population in the 1860s and 1870s had been so severe that breeding success was permanently reduced. At one time the sheer numbers of passenger pigeons in a flock was enough to discourage potential predators. Once the population was split into small, isolated remnants, however, natural predation also contributed to the species' rapid decline.

Passenger pigeon. (Photograph by John D. Cunningham. Visuals Unlimited. Reproduced by permission.)

The last individual passenger pigeon was a female named Martha, which died in the Cincinnati Zoo in 1914. It is now on display at the National Museum of Natural History in Washington, D.C.

Passive solar design

Looking into the sky on a sunny day, the notion that humans could have an "energy crisis" seems absurd. Each day, the earth receives 1.78×10^{14} kilowatts of energy, more than 10,000 times the amount needed by the whole world this year. All that is required is a way to collect and harness the energy of sunlight.

Humans have explored systems for the capture of **solar energy** for centuries. The Roman architect Vitruvius described a plan in the first century B.C. for building a bathhouse heated by sunlight. He explained that the building should "look toward the winter sunset" because that would make the bathhouse warmer in the late afternoon. More recently, water heaters operated by solar energy were built and widely sold in the early 1990s, especially in California and Florida.

Most historical examples illustrate the principles of passive solar heating, namely constructing a building so that it can take advantage of normal sunlight without the use of elaborate or expensive accessory equipment. A home built on this principle, for example, has as much window space as possible facing toward the south, with few or no windows on other sides of the house. Sunlight enters the south-facing window and is converted to heat, which is then trapped inside the house. To reduce loss of heat produced in this way, the window panes are double- or triple-glazed, that is, consist of two or three panes separated by air pockets. The rest of the house is also as thoroughly insulated as possible. In some cases, a house can be built directly into a south-facing hill so that the earth itself acts as insulation for the north-, east-, and west-facing walls.

Adjustments can also be made to take account of changing sun angles throughout the year. In the winter, when the sun is low in the sky, solar heat is needed most. In the summer, when the sun is high in the sky, heating is less important. An overhang of some kind over the south-facing window can provide the correct amount of sunlight at various times of the year. Changing seasonal temperatures can also be managed by installing insulating screens on the south-facing window. When the screens are open, they allow solar energy to come in. When they are closed (as at night), they keep heat inside the building.

The primary drawback to the use of solar energy is its variability. Often the energy supply and the energy requirements are out of balance for weeks or months depending on season, amount of cloud cover, latitude, etc. Thus, there is frequently the need for storage of energy for later use. Several technologically-simple methods for storing solar energy are commonly used in passive solar design. A large water tank on top of the house, for example, provides one way to store this energy. Sunlight warms the water during the day and the water can then be pumped into the house at night as a heat source. A heat sink such as a dark-colored masonry wall or concrete floor near the south facing windows can also enhance a passive solar system by absorbing heat during the day and slowly radiating it into the room during the night. A Trombe wall may also be installed. This masonry wall, 6-18 inches (15-46 cm) thick with gaps at the top and bottom, faces the sun. The space in front of the wall is enclosed by glass. Air between the glass and the masonry wall is heated by the sun, rises and passes into the room behind the wall through the upper gap. Cooler air is drawn from the room into the space through the lower gap. The masonry wall also acts as a heat sink.

John Arthur Passmore (1914 –)

Australian philosopher and writer

As a philosopher, John Passmore has defended Western civilization against the charge that such societies "can solve their ecological problems only if they abandon the analytical, critical approach which has been their peculiar glory and go in search of a new ethics, a new metaphysics, a new religion." We do indeed face daunting ecological crises, Passmore states, but the best hope for solving them lies in "a more general adherence to a perfectly familiar ethic."

Born in Manly, New South Wales, **Australia**, on September 9, 1914, Passmore earned his B.A. and M.A. degrees from the University of Sydney, where he taught philosophy from 1935 to 1949. He then served on the faculties of Otago University in New Zealand and the Australian National University, holding the chair of philosophy at the latter from 1959 to 1979. The best known of his many publications are *Hume's Intentions* (1952), *A Hundred Years of Philosophy* (1957), *The Perfectibility of Man* (1970), and *Man's Responsibility for Nature* (1974).

Part of Passmore's argument in *Man's Responsibility for Nature* is that people in the West, like people everywhere, cannot simply adopt a new and unfamiliar way of thinking: one must begin where one is at. He also insists that Western civilization encompasses more than one way of thinking. He argues that "central Stoic-Christian traditions are not favourable to the solution of [the West's] ecological problems..." but that these "are not the only Western traditions and their influence is steadily declining." More favorable are traditions such as Jewish thought and, especially, modern science. These are hospitable to two attitudes—a sense of stewardship and a sense of cooperation with nature—that are incompatible with the Stoic-Christian traditions, "which deny that man's relationships with **nature** are governed by any moral principles and assign to nature the very minimum of independent life."

As a champion of stewardship and cooperation with nature, Passmore sharply disagrees with those who see civilization as an enemy of nature or a blight upon it. On the contrary, Passmore sees in civilization "man's great memorials—his science, his philosophy, his technology, his architecture, his countryside...all of them founded upon his attempt to understand and subdue nature." He considers the transformation of the natural **environment** necessary and, when done with care, desirable. For there is "no good ground...for objecting to transforming as such; it can make the world more fruitful, more diversified, and more beautiful."

Passmore's case for a more responsible attitude toward nature rests, finally, on a rejection of mysticism that includes a rejection of religion and the concept of the sacred: "To take our ecological crises seriously...is to recognize, first, man's utter dependence on nature, but secondly, nature's vulnerability to human depredations—the fragility, that is, of both man and nature, for all their notable powers of recuperation. And this means that neither man nor nature is sacred or quasi-divine."

[*Richard K. Dagger*]

Pathogen

A pathogen is an agent that causes disease. Pathology is the scientific study of human disease. One could argue that anything that causes disease is therefore by definition a "pathogen." Sunlight is the environmental agent that (with excessive exposure) induces the potentially fatal skin **cancer** known as melanoma. Ordinarily, however, most people do not consider sunlight to be a pathogen. An unbalanced diet may result in nutritional deficiencies which can lead to diseases such as pellagra (caused by a niacin deficiency) and scurvy (caused by inadequate vitamin C in the diet). Nevertheless, the *failure* to consume a balanced diet is not considered to be a pathogen. Generally, most students of disease refer to biological agents when they use the term pathogen. Such agents, which include viruses, bacteria, **fungi**, protozoa, and worms, cause a tremendous diversity of diseases.

Viruses, while considered biological agents, are not cellular organisms and accordingly, are not living in the usual sense. They are tiny particles consisting of either DNA or RNA as the genetic material and a protein coat, and they are incapable of **metabolism** outside of a living cell. Pathogenic viruses cause diseases of the respiratory system such as colds, laryngitis, croup, and influenza. Skin eruptions such as measles, rubella, chicken pox, and foot-and-mouth disease are viral in origin. The long list of viral diseases include insect-borne Western equine encephalitis and yellow fever. Recently, some human cancers have been thought to be associated with viruses, perhaps because animal cancers such as the Lucké renal carcinoma and mouse mammary carcinoma are known to be caused by viruses. One such human cancer is Burkitt's lymphoma, a childhood malignancy occurring primarily in Africa, which is associated with a herpes **virus**. **AIDS** results from infection with HIV and is a pandemic viral disease.

Bacteria are true cells but their genetic material, DNA, is not packaged in a nucleus as in all higher forms of life. Not all bacteria are pathogens, but many well-known diseases are caused by bacterial infections. Tuberculosis, **cholera**, **plague**, gonorrhea, syphilis, rheumatic fever, typhus, and typhoid fever are some of the very serious diseases caused by pathogenic bacteria.

Probably 100 million cases of **malaria** occur each year primarily in Africa, Asia, and Central and South America. Malaria is caused by four **species** of the protozoan *Plasmodium*. *Amebiasis* and *giardiasis* are parasitic protozoa infections. Protozoa are single-celled animals. Thrush (*candidiasis*) is a common infection of mucous membranes with a yeast-like fungus. Valley fever (*coccidioidomycosis*) is a fungal infection generally limited to the lungs. Athlete's foot is a common skin infection caused by a fungus.

Worms that infect humans are a significant health problem in those parts of the world where there is inadequate public health protection. Examples of helminth infections are the beef and pork tapeworms. The consumption of inadequately cooked pork can result in trichinosis, which is a roundworm (nematode) infection of human muscle. Trematode flukes cause an extraordinarily important infection in Asia and Africa called **schistosomiasis** with hundreds of millions of individuals infected. Perhaps the most common parasitic helminth infection in the United States is *enterobiasis* known as pinworm or seatworm infection, which is a common condition of children with improper personal hygiene.

Many diseases caused by **microbial pathogens** can be treated with a diversity of antibiotics and other drugs. However, viral pathogens remain intractably difficult to manage with drugs.

[*Robert G. McKinnell*]

Ruth Patrick (1907 –)

American biologist and limnologist

Emphasizing the vital importance of environmental clean-up and **conservation**, Ruth Patrick has spent a lifetime facilitating cooperation among the scientific and political communities to find solutions to biospheric **pollution**. Her aggressive endeavors in freshwater research, including work on diatoms and the biodynamic cycles of rivers, have made much progress toward rectifying damage done by pollutants.

Her enthusiasm and concern for the **biosphere** began at an early age in her hometown of Kansas City, where, as a child, she conducted many expeditions through the countryside surrounding her family home. Collecting specimen materials and identifying them set the course for Patrick's future. She was fascinated by the microscopic world that could be found even in the smallest drop of water.

Patrick continued to foster her interests in science as she grew older. She attended Coker College in Hartsville, South Carolina, and earned a bachelor's degree in botany there in 1929. She then attended the University of Virginia where she earned a doctoral degree in 1934. Throughout her career, Patrick has been awarded honorary degrees from many institutions, including Princeton University and Wake Forest University. In 1975, she received the prestigious John and Alice Tyler Ecology Award (through Pepperdine University); the award amount of $150,000 is the largest amount granted for a scientific award.

Patrick was a key force in the founding of **limnology**, the scientific study of the biological, physical, and chemical conditions of freshwater. By conducting further studies, she also became widely known as an expert on diatoms, the basic food substance of freshwater organisms, and she later developed the diatometer. The diatometer is used to measure the levels of diatoms in freshwater, a measurement which is used in evaluating the pollution levels and general health of freshwater bodies. During the late 1960s and early 1970s, she acted as a consultant in both the private sector and in government, and her vast knowledge and influence enabled her to play an active role in the development of **environmental policy**. She worked with the **U.S. Department of the Interior** and served on numerous committees, including the **Hazardous Waste** Advisory Committee of the **Environmental Protection Agency** (EPA) and the Science Advisory Council of the World **Wildlife** Federation. She has often been called the "Ralph Nader of water pollution," and she has a wide reputation as a dauntless watchdog. Patrick has conducted most of her work through her offices at the Academy of Natural Sciences in Philadelphia, where she has been on staff since the late 1930s. She was the first female board chairperson at the academy.

Patrick also maintains membership in such organizations as the **National Academy of Sciences**, the National Academy of Engineering, the American Academy of Arts and Sciences, the International Limnological Society, the American Society of Limnology and Oceanography, and the American Society of Naturalists. She has been bestowed dozens of awards from schools, institutions, and organizations, and she has written four books, including *Diatoms of the United States* (with C. W. Reimer). In 1996, Patrick was presented with a National Medal of Science by President Clinton for her work in pioneering the field of limnology and inducted into the South Carolina Hall of Science and Technology. In 1999, she was awarded the Governor of South Carolina, and currently hold the Francis Boyer Chair of Limnology and Senior Curator at the National Academy of Sciences.

Peat soils

A **soil** that is derived completely from the decomposing remains of plants. Plants that commonly form peat include reeds, sedges, sphagnum moss, and grasses. The plant remains do not decompose but continue to accumulate because the wet and/or cool **environment** in which they occur is not conducive to **aerobic decomposition**. Vegetable crops are often grown on peat soils. Peat can also be harvested for

use in horticulture or as a fuel for heating and cooking. *See also* Peatlands

Peatlands

Expansive areas of **peat soils** are referred to as peatlands. These areas are often located in what were once lakes or oceans. The clay deposits from the former lake provide an impermeable layer so that water accumulates. Plants growing in this wet **environment** will not be able to decompose because of a lack of oxygen. Accumulations of plants will continue to increase the thickness of the peat deposit until a **soil** formed entirely of peat is created. These deposits can be 40 feet (12 m) or more thick. Extensive peatlands occur in Minnesota, Wisconsin, Michigan, New England, Russia, England, and Scandinavian countries.

Pedology

The scientific study of **soil** as a natural body, without emphasizing the practical uses or ecological significance of the soil. Pedology includes soil formation and morphology, its basic physical and chemical properties, its distribution, and the erosional processes affecting it without direct regard to plants or animals. Pedology provides the foundation for the study of soil as a medium of biological activity, called **edaphology**, and for the study of soil necessary in construction and **drainage** projects.

Pelagic zone

The entire water column in marine ecosystems, regardless of depth. Plants and algae in the pelagic zone directly or indirectly support most of the ocean's animal life. Because plant growth is confined to the shallow depths of the pelagic zone reached by light (epipelagic zone, 0-650 ft/0-200 m), much of the biological activity in the pelagic zone is concentrated in near-surface waters. The pelagic zone is further subdivided by depth into the mesopelagic zone (650-3,280 ft/200-1000 m), bathypelagic zone (3,280-13,125 ft/1000-4000 m) and abyssopelagic zone (greater than 13,125 ft/4000 m), each zone inhabited by a distinctive **fauna**. These deeper fauna are nourished largely by organic matter (e.g. dead **plankton**, fecal material) settling from surface waters. *See also* Littoral zone; Neritic zone; Photic zone; Phytoplankton; Zooplankton

Pentachlorophenol

One of the most widely manufactured **chemicals** in the world, PCP is used extensively as a wood preservative for telephone poles, fences, and indoor or outdoor construction materials. It has also been used for slime control in the pulp and paper manufacturing process, for weed control, termite control, and as a paint preservative. Technical grade PCP contains trace amounts of less-chlorinated phenols and certain chlorinated dioxins and **furans**. Concerns over its toxicity have curtailed the use of PCP in the United States to treat materials that humans or animals will have contact with. Readily absorbed through skin and also volatile, it is acutely toxic from dermal exposure or inhalation.

People for the Ethical Treatment of Animals

Founded in 1980 by Alex Pacheco and Ingrid Newkirk, People for the Ethical Treatment of Animals (PETA) is a nonprofit charitable organization dedicated to protecting and promoting **animal rights**. These rights are not, of course, civil or religious, but rather, the right to live free from human-caused pain or predation. To this end, PETA has mounted campaigns against the use of animals in painful and frequently fatal medical experiments, as well as in the testing of cosmetics and other products. They have also campaigned against the **trapping** of fur-bearing animals, so-called "factory farming," such as confining cattle in crowded **feedlots**, and the cruel use of animals in rodeos, carnivals, and circuses. Through its newsletter, *PETA News*, and its "Factsheets," PETA publicizes these and other abuses and encourages readers to take action. Members write to the offending organizations, organize boycotts of their products or services, and contact their political representatives in support of proposed or pending legislation regarding the treatment of animals.

Drawing many of its ideas and much of its inspiration from philosophers such as **Tom Regan** and **Peter Singer**, PETA is attempting (in Singer's words) to "expand the circle" of creatures considered worthy of respect and protection. Although other forms of discrimination, such as racism and sexism, have been widely discredited (if not yet eliminated), another form of discrimination has barely begun to be recognized. **Speciesism** is the view that one particular **species**, *Homo sapiens*, is superior to all other species and that therefore humans have the unquestionable and unlim-

ited right to use or to kill those other species for food, fur, leather, labor, or amusement. Such speciesist beliefs and attitudes are deeply rooted in our culture, Regan and Singer argue, and challenging them is often very difficult.

Animal rights advocates have been accused of putting the interests of animals above or at least on a par with those of human beings. Many critics of PETA quote, out of context, Ingrid Newkirk's statement that "a rat is a pig is a dog is a boy," thereby purporting to prove that PETA and other animal rights organizations equate the rights and interests of human and nonhuman animals. This statement of Newkirk's was actually intended to show that humans, like animals, are sentient beings because they have a central nervous system and are therefore able to feel pleasure and pain. "When it comes to having a central nervous system and the ability to feel pain, hunger, and thirst," said Newkirk, "a rat is a pig is a dog is a boy." More elaborate and extended versions of the argument about sentience can be found in Peter Singer's *Animal Liberation* (1990) and in Tom Regan's *The Case for Animal Rights* (1983). But PETA's primary aim is not to engage in philosophical disputation but to participate in political, economic, and educational campaigns on behalf of creatures who cannot defend themselves against humanly caused pain and predation.

Peptides

A chemical compound consisting of two or more amino acids joined to each other through a bond between the **nitrogen** atom of one amino **acid** to an oxygen atom of its neighbor. A more precise term describes the number of amino acid units involved. A dipeptide or tripeptide consists

Peregrine falcons on ledge, downtown Detroit, Michigan. (Photograph by Karl W. Kenyon. National Audubon Society Collection. Photo Researchers Inc. Reproduced by permission.)

of two or three amino acid units respectively. A few oligopeptides (about ten amino acid units) are of physiological importance. The antibiotics bacitracin, gramicidin S, and tyrocidin A are examples of oligopeptides. The largest polypeptides contain dozens or hundreds of amino acid units and are better known as proteins. The bond between peptide units is especially sensitive to attack by various types of corrosive poisons such as strong acids and bases.

Percina tanasi

see **Snail darter**

Percolation

The movement of water through **soil** and the unsaturated zone into and through the pores of materials in the **zone of saturation**. **Groundwater** is recharged by this movement of water through the unsaturated zone. From a soil science perspective, percolation refers to the **drainage** of initially wetted areas of soil and movement of water beyond the rooting zone of plants toward the **water table**. Sanitarians commonly use percolation, however, in reference to results of the common soil test, known as the Perk test, which evaluates the rate at which soils accept water. The rate water moves into the soil is referred to as percolation. *See also* Aquifer; Aquifer restoration; Drinking water supply; Recharge zone; Vadose zone; Water table draw-down

Peregrine falcon

The peregrine falcon (*Falco peregrinus*), a bird of prey in the family Falconidae, is one of the most wide-ranging birds in the world with populations in both the Eastern and Western Hemispheres. However, with extensive **pesticide** use, particularly DDT, beginning in the 1940s, many populations of these birds were decimated. In the United States by the 1960s, the peregrine falcon was completely extirpated from the eastern half of the country because DDT and related compounds, which are amplified in the **food chain/web**,

caused the birds' eggshells to become thin and fragile. This led to reproductive failures, as eggs were crushed in the nest during incubation. Prior to the DDT-induced losses, there were about 400 breeding pairs of peregrine falcons in the eastern United States. In the early 1970s there were over 300 active nests in the western states, but within a single decade that number dropped to 200. The numbers continued to decline, and in 1978 there were no breeding pairs of peregrine falcons in the eastern United States. By 1984, due to reintroduction efforts, there were 27 nesting pairs, and in 1985, 38 nesting pairs were present in the east with at least 16 pairs fledging young. Also in 1985, 260 young, captive-raised peregrine falcons were released into the wild, 125 in the eastern states, and 135 in the west. By 1986, 43 pairs were nesting, and 25 of those pairs fledged 53 young. By 1991, over 100 breeding pairs were found in the east, and 400 pairs were found in the west. The increase of peregrine falcons has brought the numbers up to 215 breeding pairs in the mid-west regions.

The recovery success of the peregrine falcon is due largely to the efforts of two groups, the Peregrine Fund based at Cornell University in Ithaca, New York, and the **Canadian Wildlife Service** at Camp Wainwright in Alberta. Much of their research centered on captive breeding for release in the wild and finding ways to induce the falcons to nest and raise young in their former range. With great patience, and limited early success, the projects paid off.

The restoration projects also yielded much valuable information as well as innovative approaches to reestablishing peregrine falcon populations. For captive breeding, falcons trapped as nestlings stood a much better chance of reproducing in captivity than when trapped as flying immatures or adults. Since **habitat** destruction and human encroachment limit potential nesting sites—which typically are cliff ledges—researchers found that a potential, and ultimately successful, alternative nest site was the window ledge of tall, city buildings. These locations mimic their natural nest sites, and these "duck hawks," as they were once called, had a readily available prey in their new urban **ecosystem**. Peregrine falcons immediately began killing rock doves for food, which some saw as a service to the cities, since these "pigeons" tended to be regarded as a "nuisance" **species**.

Since it began in the 1970s, this captive breeding and release program has become well established, with over 4,000 captive-bred peregrine falcons released over the past three decades. In August of 1999, the peregrine falcon was removed from the **Endangered Species** list by the U.S. **Fish and Wildlife Service**.

Perfluorooctane sulfonate

Fluoro-organic **chemicals** such as perfluoro-octane sulfonate ($C_8F_{17}SO_3H$)(PFOS), have been used since the 1950s in soil- and stain-resistant coatings for fabrics, carpets, and leather (2.4 million lb [1 millionkg] in 2000), as well as in oil- and grease-resistant coatings for paper products (about 2.7 million lb [1.2 million kg]in 2000). Though PFOS is mostly applied to products in textile mills, leather tanneries, finishers, and carpet manufacturing facilities, the use of Scotchgard fabric protector also allows for the use of PFOS by the consumer. Additional uses of PFOS and related compounds in specialized industrial applications (1.5 millions lb [680,000 kg] in 2000) include fire-fighting foams, mining and oil well surfactants, **acid** mist suppressants for metal plating and electronic etching baths, alkaline cleaners, floor polishes, photographic film, denture cleaners, and shampoos, and ant insecti cide.

In May 2000, 3M Corporation announced that, by 2002, it would phase out a group of perfluorinated chemicals, including PFOS, used in Scotchgard and other products. 3M Corporation is the only manufacturer of PFOS in the United States. All of the fluorochemicals that are being phased out either use PFOS in their manufacture or breakdown to PFOS, which is persistent in the **environment** due to the high energy of the carbon-fluorine bond. 3M Corporation had conducted a major research effort to characterize the environmental presence, environmental and human effects, and environmental fate of PFOS; the results of those research efforts indicated that continued use of PFOS could potentially have severe long-term consequences to human health and the environment.

PFOS, unlike most other persistent organic compounds, does not accumulate in fats, but as a surfactant with both lipophilic and hydrophobic tendencies, binds to blood proteins and accumulates in the liver and gall bladder. In a study published in 2001, PFOS was shown to be present in each of 65 human blood samples from persons who had not been industrially exposed to PFOS. In another 2001 study, 247 tissue samples from marine mammals collected from

Florida, California, and Alaskan coastal waters, as well as the northern Baltic Sea, the Arctic, and Sable Island in Canada were analyzed for PFOS. PFOS was found in the blood and livers of nearly all of the marine mammals. Although animals from sites nearer to developed and industrialized regions had higher levels of PFOS in their tissues, animals from even the most remote locations, including the Arctic Ocean, were found to have contain significant levels of PFOS. Near-shore animals had higher concentrations those that lived off shore. Further, fresh-water **species** had higher concentrations than ocean species. PFOS was also found in samples of 21 species of fish-eating birds, including eagles, ospreys, albatrosses, gulls, herons, loons, ibises, and gannets that had been collected from locations in the United States and the central Pacific Ocean. Birds in more urbanized areas had higher concentrations. Birds from the central Pacific also had measurable PFOS levels, indicating the presence of PFOS in remote marine locations. The lowest concentrations of PFOS were found in an insect-eating gull. Contamination levels observed in these studies were lower than those known to be toxic in **wildlife**; however, additional studies are required to determine the long-term effects of low-level exposure to PFOS.

Toxicological studies have shown that PFOS can result in adverse developmental, reproductive, and **systemic** effects. In a study of two generations of rats and the effects of PFOS on reproduction, PFOS was found to cause postnatal death as well as have detrimental developmental effects. At the highest doses (3.2 mg/kg/day), the offspring in the first generation of rats died, while at one-half of the highest dose (1.6 mg/kg/day), almost one-third of the offspring in the first generation died. At a lower dose (0.4 mg/kg/day), PFOS resulted in lower pup weight compared to controls. Reversible delays in reflex and physical development were also observed in this study.(

In Rhesus monkey studies, no monkeys survived more than three weeks at 10 mg/kg/day or more than seven weeks at doses of 4.5 mg/kg/day. Cynomolgus monkeys also died at a dose of 0.75 mg.kg.day, after first becoming listless and exhibiting loss of appetite. Both species of monkeys showed liver enlargement and reduced cholesterol levels in the blood.

From the results of the toxicological studies and the survey of animals and human blood samples throughout the world, a representative of the U.S. **Environmental Protection Agency** (EPA) stated that PFOS exhibits "persistence, **bioaccumulation**, and toxicity to an extraordinary degree". Research is being conducted to develop safer substitutes for PFOS.

Permaculture

Permaculture is an approach to land management that creates high-yielding, low-energy, self-perpetuating systems by which the functions of animals, plants, humans, and Earth are integrated to maximize their value and create sustainable human habitats. Permaculture brings together disciplines relating to food, shelter, energy, water, **waste management**, economics, and social sciences. It aims to maximize a site's productivity, while maintaining ecosystems and restoring damaged land to a healthy, life-promoting state. Bill Mollison has written five books on this topic: *Introduction to Permaculture, Permaculture: A Designer's Manual*; *Permaculture One*; *Permaculture Two;* and *Permaculture: A Practical Guide for a Sustainable Future.* Several permaculture organizations and model projects exist around the world.

The term was first coined in 1972 by Bill Mollison of Tasmania, **Australia**, by merging the terms, "permanent" and "agriculture." Although originally developed for small subsistence farms, the practice has expanded to apply to gardens and urban settings. Some consider it a lifestyle as much as a design approach.

Permaculture principles focus on designs for small-scale intensive systems that are labor-efficient and use biological resources instead of **fossil fuels**. These designs stress ecological connections and closed energy and material loops. The core of permaculture is integrating working relationships and connections between all things. Each component in a system performs multiple functions, and each function is supported by many elements. Key to efficient permaculture design is observing and replicating natural ecosystems. Designers maximize diversity with polycultures, stress efficient energy planning for houses and settlements, and use and accelerate natural plant **succession**. The philosophy behind permaculture is one of working with rather than against **nature**, looking at systems in all of their functions, and using systems for multiple purposes. It is a method of agriculture that aims to endure without constant human inputs and does not deplete the land.

According to Mollison, permaculture has several distinct characteristics. It makes the most of small landscapes, using intensive practices. Ideally, nothing is wasted, and everything is arranged so that the least amount of effort is exerted and the highest yield from the systems is gained. Systems are designed that use and complement the natural systems that are present. For example, storm water is controlled with planted swales (marshy depressions), not concrete drains. The design harvests the natural flows of energy through the landscape (such as sunlight, rain, and plant and animal behaviors). Diversity is promoted in plant **species**, varieties, yield, **microclimate**, and **habitat**. Permaculture maintains that, in a **monoculture**, a single species cannot make full use of all of the available energy and nutrients. Wild or seldom-selected animal and plant species are used. Each element performs many functions in the system. For example, a fruit tree provides not only a crop, but also wind shelter, a trellis, **soil** conditioning, and shade and roosting for birds. The long-term evolution of the land is recognized, and those changes are incorporated in planning. All activities involving the land—agriculture, animal husbandry, extant **forest management**, animal cropping, and landform engineering—are integrated. Difficult landscapes (rocky, marshy, marginal, or steep) not typically suited to other systems are utilized. Permaculture involves long-term and evolving land-use planning, using diverse **flora** and **fauna** in various ways at different times, recognizing that different species use different nutrients and resources.

Permaculture systems typically feature: passive energy systems and minimal external energy needs; on site **climate** control; planned future developments; on-site provision for food self-sufficiency; safe on-site disposal of wastes; low-maintenance structures and grounds; assured and conserved water supply; and control and direction of fire, cold, excess heat, and wind factors.

Permaculture originated as a strategy for designing systems for "permanent" or perennial agriculture, by creating **agroforestry** systems using tree crops, shrubs, vines and, herbaceous plants in highly productive symbiotic assemblages. The practice was originally oriented to subsistence farms in Tasmania, which typically were small and on poor land. It was then extended to include other landscapes, urban settings, and climates worldwide, and has even been applied to other systems such as houses and factories.

Permaculture as a Life Philosophy

Some consider permaculture a life philosophy. In this context, permaculture emphasizes putting oneself into a symbiotic relationship with Earth and one's community. Permaculture is oriented to place, with reliance on native plants and a close awareness of the **ecosystem**. It revolves around self-reliance, growing food and building attractive energy-efficient structures from local materials. Designing a permaculture landscape begins with assessing a site's native features (such as soil structure, microclimates, cycles of decay, and existing flora and fauna), in order to take advantage of existing resources. This assessment also helps in selecting and adapting technologies to the site. These technologies might include methods of **composting**, gardening, irrigating, or generating electricity. Multifunctional living systems abound in a typical permaculture design.

Examples of Permaculture Practices and Approaches

Animals are raised for their value as producers of food, skins, and manure, and as pollinators, heat sources, gas producers, earth tillers, and **pest** controller. For example, rabbits raised in a rabbit hutch are fed kitchen scraps. Their droppings fall into worm bins (vermiculture) as fodder for worms, and the resulting worm castings are used to fertilize gardens. In the winter, the rabbits are harvested for their meat and fur. As another example, movable chicken hutch can be used to place chickens in gardens where they effectively till and fertilize the soil.

Particular varieties of trees are chosen for their fuel, forage, material (for fences, structures and shelters), heat reflector and windbreak values, as well as for crop diversification. When they are young, the trees may act as hedgerows, then grow to serve as a fuel source. Plants provide many services for other plants. They act as trellises, for other screen and shade them, provide nutrients, cross-fertilize them (as happens with varieties of plums and nuts), help to repel pests, prevent **erosion**, and provide spare parts (grafts) for other plants. Fruit trees and vines are planted strategically around a house to provide shade. In a home's front yard, attractive gardens feature high-yielding food, medicinal and culinary plants where they are easily accessed. Some crops are planted for their self-propagating patterns, such as leeks, onions, potatoes, and garlic.

Water harvesting is an essential function in a permaculture landscape, and is supported by as many components as possible. **Filtration** of water for animals may be provided with shells and water plants. Water pathways are traced, and systems are created for collecting it. Swales may direct rain water and run-off to fruit trees. Run-off water from culverts may be directed to ponds where water plants and fish are raised, and where it can be used for **irrigation** and firefighting. Water can be collected from roofs. Composting **toilets** and septic systems with planted **leaching** beds can be employed.

Insects and crops are used to aerate the soil. Mulching, growing green crops, composting, and strategic planting are employed to build soil health. Permaculture grows forests and shrubs to protect the soil, and uses plows that do not turn the soil. Food crops, such as corn and legumes, are chosen for their low-maintenance qualities and their ability to fix **nitrogen** in the soil.

Permaculture emphasizes reactive homes, sheltered from cold winds with windbreak planting. Such homes are oriented on an east-west axis facing the sun, usually with a greenhouse, and are well-sealed. They should use few resources not found on site. Shelters can be built into the earth, with living turf roofs. Sometimes, living trees and plants are used to create shelters.

Permaculture offers an **environmental design** practice for making better use of resources in a variety of growing settings. What started as a method for cultivating **desert** land has grown into a system that integrates living systems, fostering greater consciousness of ecosystems and helping to ensure economic and ecological sustainability for its practitioners. Permafrost

Permafrost is any ground, either of rock or **soil**, which is perennially frozen. Continuous permafrost refers to areas which have a continuous layer of permafrost. Discontinuous permafrost occurs in patches. It is believed that continuous permafrost covers approximately 4% of the earth's surface and can be as deep as 3,281 ft (1,000 m), though normally it is much less. Permafrost tends to occur when the mean annual air temperature is less than the freezing point of water. Permafrost regions are characterized by a seasonal thawing and freezing of a surface layer known as the active layer which is typically 3–10 ft (1–3 m) thick.

Permanent retrievable storage

Permanent retrievable storage is a method for handling highly toxic hazardous wastes on a long-term basis. At one time, it was widely believed that the best way of dealing with such wastes was to seal them in containers and either bury them underground or dump them into the oceans. However, these containers tended to leak, releasing these highly dangerous materials into the **environment**.

The current method is to store such wastes in a quasi-permanent manner in salt domes, rock caverns, or secure buildings. This is done in the expectation that scientists will eventually find effective and efficient methods for converting these wastes into less hazardous states, in which they can then be disposed of by conventional means. One chemical for which permanent retrievable storage has been used so far is the group of compounds known as polychlorinated biphenyl (PCB)s.

Permanent retrievable storage has its disadvantages. Hazardous wastes so stored must be continuously guarded and monitored in order to detect breaks in containers or leakage into the surrounding environment. In comparison with other disposal methods now available for highly toxic materials, however, permanent retrievable storage is still the preferred alternative means of disposal. *See also* Hazardous waste site remediation; Hazardous waste siting; NIMBY; Toxic use reduction legislation

Permeable

In **soil** science, permeable is a qualitative description for the ease with which water or some other fluid can pass through soil. Permeability in this context is a function not only of the total pore volume but also of the size and distribution of the pores. In geology, particularly with reference to **groundwater**, permeability is the ability of water to move through any water-bearing formation, rock, or unconsolidated material. This condition can be measured in the laboratory by measuring the volume of water that flows through a sample over a certain period of time. *See also* Aquifer; Recharge zone; Soil profile; Vadose zone; Zone of saturation

Peroxyacetyl nitrate (PAN)

The best known member of a class of photochemical oxidizing agents known as the peroxyacyl **nitrates**. The peroxyacyl nitrates are formed when **ozone** reacts with **hydrocarbons**

such as those found in unburned **petroleum**. They are commonly found in **photochemical smog**. The peroyxacyl nitrates attack plants, causing spotting and discoloration of leaves, destruction of flowers, reduction in fruit production and seed formation, and death of the plant. They also cause red, itchy, runny eyes and irritated throats in humans. Cardiac and respiratory conditions, such as **emphysema** and chronic **bronchitis**, may result from long-term exposure to the peroxyacyl nitrates. *See also* Air pollution; Los Angeles Basin

Persian Gulf War

The Persian Gulf War in 1991 had a variety of environmental consequences for the Middle East. The most devastating of these effects were from the **oil spills** and oil fires deliberately committed by the Iraqi army. There were extensive press coverage of these events at the time, and the United States accused the Iraqis of "environmental terrorism." These accusations were seen by some as propaganda effort, and there was almost certainly some political motivation to both how the damage was estimated and how it was characterized during the war. But it is clear now that the note of outrage often struck by the Allies was not out of place. The devastation, though not as extensive as originally supposed, was still substantial.

The Iraqis began discharging oil into the Persian Gulf from the Sea Island Terminal and other supertanker terminals off the coast of Kuwait on January 23, 1991. Allied bombers tried to limit the damage by striking at pipelines carrying oil to these locations, but the flow continued throughout the war. Estimates of the size of the spill have varied widely and the controversy still continues, with a number of diplomatic and political pressures preventing many government agencies from committing themselves to specific figures. But it now seems likely that this was the worst oil spill in history, probably 20 times larger than the ***Exxon Valdez*** spill in **Prince William Sound**, Alaska, and twice the size of the 1979 spill from the blowout of Ixtoc I well in the Gulf of Mexico.

Whatever the actual size of the spill, it occurred in an area that was already one of the most polluted in the world. Oil spills and oil dumping are common in the Persian Gulf; it has been estimated that as many as two million barrels of oil are spilled in these waters every year. Some ecologists believe that the **ecosystem** in the area has a certain amount of **resistance** to the effects of **pollution**. Other scientists have maintained that the high level of **salinity** in the Gulf will prevent the oil from having many long-term effects and that the warm water will increase the speed at which the oil

Two men cleaning a bird soaked in oil that was spilled into the Persian Gulf by Iraq during the Persian Gulf War. (Photograph by Wesley Bocxe, National Audubon Society Collection. Photo Researchers Inc. Reproduced by permission.)

degrades. But the Gulf has a slow circulation system and large areas are very shallow; many scientists and environmentalists have predicted that it will be many years before the water can clear itself.

The spill killed thousands of birds within months after it began, and it had an immediate and drastic effect on **commercial fishing** in the region. Oil soaked miles of coastline; coral reefs and **wetlands** were damaged, and the seagrass beds of the Gulf were considered particularly vulnerable. Mangrove swamps, migrant birds, and **endangered species** such as green turtles and the dugong, or sea cow, are still threatened by the effects of the spill. The Saudi Arabian government has protected the water they draw from the Gulf for **desalinization**, but little has been done to limit or alleviate the environmental damage. This has been the result, at least in part, of a shortage of resources during and after the war, as well as obstacles such as floating mines and shallow waters which restricted access for boats carrying cleanup equipment.

At the end of the war, the retreating Iraqi army set over 600 Kuwaiti oil **wells** on fire. When the last burning well was extinguished on November 6, 1991, these fires had been spewing oil **smoke** into the **atmosphere** for months, creating a cloud which spread over the countries around the Gulf and into parts of Asia. It was thought at the time that the cloud of oil smoke would rise high enough to cause global climatic changes. Carl Sagan and other scientists, who had first proposed the possibility of a **nuclear winter** as one of the consequences of a nuclear war, believed that rain patterns in Asia and parts of Europe would be affected by the oil fires, and they predicted failed harvests and widespread starvation as a

result. Though there was some localized cooling in the Middle East, these kinds of global predictions did not occur, but the smoke from the fire has still been an environmental disaster for the region. **Air quality** levels have caused extensive health problems, and **acid rain** and **acid deposition** have damaged millions of acres of forests in Iran.

The oil fires and oil spills were not the only environmental consequences of the Persian Gulf War. The movement of troops and military machinery, especially tanks, damaged the fragile **desert** soils and increased wind **erosion**. Wells sabotaged by the Iraqis released large amounts of oil that was never ignited, and lakes of oil as large as half a mile wide formed in the desert. These lakes continue to pose a hazard for animals and birds, and tests have shown that the oil is seeping deeper into the ground, causing long-term contamination and perhaps, eventually, **leaching** into the Gulf. *See also* Gulf War syndrome

Persistent compound

A persistent compound is slow to degrade in the **environment**, which often results in its accumulation and deleterious effects on human and **environmental health** if the compound is toxic. Toxic metals such as **lead** and **cadmium**, organochlorides such as **polychlorinated biphenyls** (PCBs), and **polycyclic aromatic hydrocarbons** (PAHs) are persistent compounds.

Persistent molecules are termed recalcitrant if they fail to degrade, metabolize, or mineralize at significant rates. Their compounds can be transported through the environment over long periods of time and over long distances, resulting in long-term exposure and possible changes in organisms and ecosystems. However, organisms and ecosystems may adapt to the compounds, and deleterious effects may weaken or even disappear.

Compounds may be persistent for several reasons. A compound can be persistent due to its chemical structure. For example, in a molecule, the number and arrangement of **chlorine** ions or hydroxyl groups can make a compound recalcitrant. It can also persist due to unfavorable environmental conditions such as **pH**, temperature, ionic strength, potential for **oxidation reduction reactions**, unavailability of nutrients, and absence of organisms that can degrade the compound.

The period of persistence can be expressed as the time required for half of the compound to be lost, the **half-life**. It is also often expressed as the time for detectable levels of the compound to disappear entirely. Compounds are classified for environmental persistence in the following categories:(1) Not degradable, compound half-life of several centuries; (2) Strong persistence, compound half-life of several years; (3) Medium persistence, compound half-life of several months; and (4) Low persistence, compound half-life less than several months.

Non-degradable compounds include metals and many radioisotopes, while semi-degradable compounds (of medium to strong persistence) include PAHs and chlorinated compounds. Compounds with low persistence include most organic compounds based on **nitrogen**, sulfur, and **phosphorus**.

In general, the greater the persistence of a compound, the more it will accumulate in the environment and the **food chain/web**. Non-degradable and strongly persistent compounds will accumulate in the environment and/or organisms. For example, because of **bioaccumulation** through the food chain, dieldrin can reduce populations of birds of prey. Compounds with intermediate persistence may or may not accumulate, while non-persistent pollutants generally do not accumulate. However, even compounds with low persistence can have long-term deleterious effects on the environment. **2,4-D** and **2,4,5-T** can cause **defoliation**, which may result in **soil erosion** and long-term effects on the **ecosystem**.

Chemical properties of a compound can be used to assess persistence in the environment. Important properties include: (1) rate of biodegradation (both **aerobic** and **anaerobic**); (2) rate of hydrolysis; (3) rate of oxidation or reduction; and (4) rate of photolysis in air, soil, and water. In addition, the effects of key parameters, such as temperature, concentration, and pH, on the rate constants and the identity and persistence of transformation products should also be investigated. However, measured values for these properties for many persistent compounds are not available, since there are thousands of **chemicals**, and the time and resources required to measure the desired properties for all the chemicals is unrealistic. In addition, the data that are available are often of variable quality.

Persistence of a compound in the environment is dependent on many interacting environmental and compound-specific factors, which makes understanding the causes of persistence of a specific compound complex and in many

cases incomplete. *See also* Chronic effects; Heavy metals and heavy metal poisoning; Toxic substance

Persistent organic pollutants

Persistent organic pollutants (POPs) are man-made organic compounds that persist in the natural **environment** for long periods of time. Because of their long-lasting presence in air, water, and **soil**, they accumulate in the bodies of fish, animals, and humans over time. Exposure to POPs can create serious health disorders throughout the tiers of the food web. In human beings, POPs can cause **cancer**, autoimmune deficiencies, kidney disorders, **birth defects**, and other reproductive problems.

Because these **chemicals** are derived from manufacturing industries, **pesticide** applications, waste disposal sites, spills, and **combustion** processes, POPs are a global problem. Many POPs are carried long distances through the **atmosphere**. They tend to move from warmer climates to colder ones, which is why even remote regions such as the Arctic contain significant levels of these contaminants. Because of the global creation and transmission of POPs, no country can protect itself against POPs without assistance. An international commitment is essential for eradication of this problem.

In the early 1990s the Organization for Economic Cooperation and Development (OECD), **United Nations Environment Programme** (UNEP), World Health Organization (WHO), and other groups began to assess the impacts of hundreds of chemicals, including POPs. In 1998 36 countries participated in the POPs Protocol, sponsored by the **Convention on Long-range Transboundary Air Pollution**. The purpose was to build an international effort toward controlling POPs in the environment.

In 2001, led by the UNEP, over 100 countries participated in the Stockholm Convention on Persistent Organic Pollutants. The proposal will become a legally binding agreement upon its ratification by 50 or more countries. It is considered by many to be a landmark human-health document of international proportions. Research will address the most effective ways to reduce or eliminate POP production, various import/export issues, disposal procedures, and the development of safe, effective, alternative chemical compounds.

The screening criteria for POP designation are: the potential for long-range atmospheric transport, persistence in the environment, bioaccumlation in the tissues of living organisms, and toxicity. Many chemicals volatilize, which increases the concentrations of these chemicals in the air. Longevity is measured by a chemical's **half-life**, or how much time passes before half of the original amount of a chemical **discharge** or **emission** breaks down naturally and dissipates from the environment. The minimum half-life for a POP in water is two months; for soil or **sediment** it is about six months. Several POPs have half-lives as long as 12 years. Animals accumulate POPs in their fatty tissue (**bioaccumulation**); these POPs are then consumed and reconcentrated by higher-order animals in the food chain (**biomagnification**). In some **species**, biomagnification can result in concentrations up to one million times greater than the background value of the POP. Most humans are exposed through consumption of food products (especially meat, fish, and dairy products) that contain small amounts of these chemicals.

The Stockholm Convention calls for the immediate ban on production and use of 12 POPs (known as the "dirty dozen"): aldrin, dieldrin, endrin, DDT, **chlordane**, heptachlor, **mirex**, **toxaphene**, hexachlorobenzene (HCB), **polychlorinated biphenyls** (PCBs), polychlorinated dioxins, and **furans**. The convention did acknowledge, however, certain health-related use exemptions until effective, environmentally friendly substitutes can be found. For example, DDT can still be applied to control malarial mosquitoes subject to WHO guidelines. Electrical transformers that contain PCBs can also be used until 2025, at which point any old transformers that are still active must be replaced with PCB-free equipment.

A brief description of the 12 banned POPs is shown below:

- Aldrin was a commonly used pesticide for the control of termites, corn rootworm, grasshoppers, and other insects. It has been proven to cause serious health problems in birds, fish, and humans. Aldrin biodegrades in the natural environment to form dieldrin, another POP
- Dieldrin was applied extensively to control insects, especially termites. Its half-life in soil is about five years. Dieldrin is especially toxic to birds and fish.
- Endrin, another insecticide, is used to control insects and certain rodent populations. It can be metabolized in

animals, however, which reduces the risk of bioaccumulation. It has a half-life of about 12 years.

- DDT, also known as dichlorodiphenyl trichloroethane, was applied during World War II to protect soldiers against insect-borne diseases. In the 1960s and 1970s its use on crops resulted in dramatic decreases in bird populations, including the **bald eagle**. DDT is still being manufactured today and is a chemical intermediate in the manufacture of dicofol. Regions that want to continue using DDT for public-health purposes include Africa, China, and India (mosquitoes, however, are becoming resistant to DDT in these areas).
- Chlordane is a broad-spectrum insecticide used in termite control. Its half-life is about one year. Chlordane is easily transported through the air and suspected of causing immune system problems in humans.
- Heptachlor was applied to control **fire ants**, termites, and mosquitoes and has been used in closed industrial electrical junction boxes. Its production has been eliminated in most countries.
- Mirex was used as an insecticide to control fire ants and termites. It is also a fire-retardant component in **rubber**, **plastics**, and electrical goods. It is a very stable POP with a half-life of up to 10 years.
- Toxaphene is an insecticide that was widely used in the United States in the 1970s to protect cereal grains, cotton crops, and vegetables. Toxaphene has a half-life of 12 years. Aquatic life is especially vulnerable to toxaphene toxicity.
- Hexachlorobenzene, also called HCB, was introduced in the 1940s to treat seeds and kill **fungi** that damaged crops. It can also be produced as a by-product of chemical manufacturing. It is suspected of causing reproductive problems in humans.
- Polychlorinated biphenyls, commonly referred to as PCBs, were used extensively in the electrical industry as a heat exchange fluid in transformers and capacitors. They were also used as an additive in plastics and paints. PCBs are no longer produced but are still in use in many existing electrical systems. Thirteen varieties of PCBs create dioxin-like toxicity. Studies have shown PCBs are responsible for immune system suppression, developmental neurotoxicity, and reproductive problems.
- Polychlorinated dibenzo-p-dioxins, usually shortened to the term "dioxins," are chemical by-products of incomplete combustion or chemical manufacturing. Common sources of dioxins are municipal and **medical waste** incinerators, backyard burning of trash, and past emissions from elemental **chlorine** bleach pulp and paper manufacturing. A dioxin's half-life is typically 10–12 years. Related health problems can include birth defects, reproductive problems, immune and **enzyme** disorders, and increased cancer risk.
- Polychlorinated dibenzofurans, usually shortened to "furans" or "PCDFs," are structurally similar to dioxins and by-products of the same processes as for dioxins. The health impacts of dibenzofuran toxicity are considered to be similar to those of dioxins. Over 135 types of PCDFs are known to exist.

The UNEP and other world organizations are continuing to look for safer and more economically viable alternatives to POPs. Manufacturing facilities are being upgraded with cleaner technologies that will reduce or eliminate emissions. Focus is also being placed on regulating the international trade of hazardous substances. Disposal is also an issue; poorer countries don't have the money or proper technological resources to dispose of the growing accumulations of obsolete toxic chemicals. The UNEP is working creatively with countries to secure financing to introduce alternative products, technology, methods enforcement, and critical infrastructure. Research sponsored by UNEP studies the chemical characteristics of current POPs so that chemical companies will be less likely to create new POPs.

The Convention on Long-range Transboundary **Air Pollution** has been extended by eight protocols, including the 1998 protocol on POPs. The third meeting of an ad-hoc group of experts on POPs was held in 2002. These scientists continue to research other chemicals that may qualify in the future as POPs.

Current technical review activities focus on the following chemicals:

- Ugilec, which was used in capacitors, transformers, and as a hydraulic fluid in underground mining. It was originally thought to be a safe replacement for PCBs.
- Hexachlorobutadiene (HCBD) was used to recover chlorine-bearing gas from chlorine plants. It is very toxic to aquatic life. HCBD is on national priority lists for some countries, such as Canada.
- Pentabromodiphenyl ether (PentaBDE) is sold as a brominated flame retardant. Its use has doubled in the last 10–15 years. This compound volatilizes easily and enters the air long after the disposal of treated products.
- Pentachlorobenzene (PeCB) was used as a **fungicide**, flame retardant, and as a component in dielectric fluids. Although it is no longer being produced, there is still an abundance of PeCB in the environment. It is probably released through **landfill** leaching/degassing or incineration.
- Polychlorinated naphthalenes (PCNs) are structurally similar to PCBs. In the 1980s PCNs were a component of products called Halowax, Nibren Wax, and Seekay Wax. Uses included wood preservation, electroplating, dye carriers, and wire insulation. Major points of release are old electrical equipment or incineration.

- Short-chain chlorinated paraffins (SCCP) are still being used today in the rubber, leather, and metal-working industries, especially in China. No suitable substitutes have been developed yet.
- Polychlorinated terphenyls (PCTs) are very similar in structure and chemical behavior to PCBs. Over 8,000 different varieties of PCTs theoretically exist. PCTs have not been commercially produced since the 1980s, but are still part of aging electrical capacitors and transformers.

Pest

A pest is any organism that humans consider destructive or unwanted. Whether or not an organism is considered a pest can vary with time, geographical location, and individual attitude. For example, some people like pigeons, while others regard them as pests. Some pests are merely an inconvenience. In the United States, mosquitoes are thought of as pests because they are an annoyance, not because they are dangerous. The most dangerous pests are those that carry disease or destroy crops. One direct way of controlling pests is by **poisoning** them with toxic **chemicals** (pesticides). A more environmentally sensitive approach is to find natural predators that can be used against them (biological controls). *See also Bacillus thuringiensis*; Integrated pest management; Population biology

Pesticide

Pesticides are **chemicals** that are used to kill insects, weeds, and other organisms to protect humans, crops, and livestock. There have been many substantial benefits of the use of pesticides. The most important of these have been: (1) an increased production of food and fibre because of the protection of crop plants from pathogens, **competition** from weeds, **defoliation** by insects, and parasitism by nematodes; (2) the prevention of spoilage of harvested, stored foods; and (3) the prevention of debilitating illnesses and the saving of human lives by the control of certain diseases.

Unfortunately, the considerable benefits of the use of pesticides are partly offset by some serious environmental damages. There have been rare but spectacular incidents of toxicity to humans, as occurred in 1984 at **Bhopal, India**, where more than 2,800 people were killed and more than 20,000 seriously injured by a large **emission** of poisonous methyl isocyanate vapor, a chemical used in the production of an agricultural insecticide.

A more pervasive problem is the widespread environmental contamination by persistent pesticides, including the presence of chemical residues in **wildlife**, in well water, in produce, and even in humans. Ecological damages have included the **poisoning** of wildlife and the disruption of ecological processes such as productivity and **nutrient** cycling. Many of the worst cases of environmental damage were associated with the use of relatively persistent chemicals such as DDT. Most modern pesticide use involves less-persistent chemicals.

Pesticides can be classified according to their intended **pest** target:

- fungicides protect crop plants and animals from fungal pathogens;
- herbicides kill weedy plants, decreasing the competition for desired crop plants;
- insecticides kill insect defoliators and vectors of deadly human diseases such as **malaria**, yellow fever, **plague**, and typhus;
- acaricides kill mites, which are pests in agriculture, and ticks, which can carry encephalitis of humans and domestic animals;
- molluscicides destroy snails and slugs, which can be pests of agriculture or, in waterbodies, the vector of human diseases such as schistosomiasis;
- nematicides kill nematodes, which can be **parasites** of the roots of crop plants;
- rodenticides control rats, mice, gophers, and other rodent pests of human habitation and agriculture;
- avicides kill birds, which can depredate agricultural fields;

- antibiotics treat bacterial infections of humans and domestic animals.

The most important use-categories of pesticides are in human health, agriculture, and forestry:

Human Health

In various parts of the world, **species** of insects and ticks play a critical role as vectors in the transmission of disease-causing pathogens of humans. The most important of these diseases and their vectors are: (1) malaria, caused by the protozoan *Plasmodium* and spread to humans by an *Anopheles*-mosquito vector; (2) yellow fever and related viral diseases such as encephalitis, also spread by mosquitoes; (3) trypanosomiasis or sleeping sickness, caused by the protozoans *Trypanosoma* spp. and spread by the tsetse fly *Glossina* spp.; (4) plague or black death, caused by the bacterium *Pasteurella pestis* and transmitted to people by the flea *Xenopsylla cheops*, a parasite of rats; and (5) typhoid fever, caused by the bacterium *Rickettsia prowazeki* and transmitted to humans by the body louse *Pediculus humanus*.

The incidence of all of these diseases can be reduced by the judicious use of pesticides to control the abundance of their vectors. For example, there are many cases where the local abundance of mosquito vectors has been reduced by the application of insecticide to their aquatic breeding **habitat**, or by the application of a persistent insecticide to walls and ceilings of houses, which serve as a resting place for these insects. The use of insecticides to reduce the abundance of the mosquito vectors of malaria has been especially successful, although in many areas this disease is now re-emerging because of the **evolution** of tolerance by mosquitoes to insecticides.

Agriculture

Modern, technological agriculture employs pesticides for the control of weeds, arthropods, and plant diseases, all of which cause large losses of crops. In agriculture, arthropod pests are regarded as competitors with humans for a common food resource. Sometimes, defoliation can result in a total loss of the economically harvestable agricultural yield, as in the case of acute infestations of locusts. More commonly, defoliation causes a reduction in crop yields. In some cases, insects may cause only trivial damage in terms of the quantity of **biomass** that they consume, but by causing cosmetic damage they can greatly reduce the economic value of the crop. For example, codling moth (*Carpocapsa pomonella*) larvae do not consume much of the apple that they infest, but they cause great esthetic damage by their presence and can render produce unsalable.

In agriculture, weeds are considered to be any plants that interfere with the productivity of crop plants by competing for light, water, and nutrients. To reduce the effects of weeds on agricultural productivity, fields may be sprayed with a **herbicide** that is toxic to the weeds but not to the crop plant. Because there are several herbicides that are toxic to dicotyledonous weeds but not to members of the grass family, fields of maize, wheat, barley, rice, and other grass-crops are often treated with those herbicides to reduce weed populations.

There are also many diseases of agricultural plants that can be controlled by the use of pesticides. Examples of important fungal diseases of crop plants that can be managed with appropriate fungicides include: (1) late blight of potato, (2) apple scab, and (3) *Pythium*-caused seed-rot, damping-off, and root-rot of many agricultural species.

Forestry

In forestry, the most important uses of pesticides are for the control of defoliation by epidemic insects and the reduction of weeds. If left uncontrolled, these pest problems could result in large decreases in the yield of merchantable timber. In the case of some insect infestations, particularly spruce budworm (*Choristoneura fumiferana*) and **gypsy moth** (*Lymantria dispar*), repeated defoliation can cause the death of trees over a large area of forest. Most herbicide use in forestry is for the release of desired conifer species from the effects of competition with angiosperm herbs and shrubs. In most places, the quantity of pesticide used in forestry is much smaller than that used in agriculture.

Pesticides can also be classified according to their similarity of chemical structure. The most important of these are:

- Inorganic pesticides, including compounds of **arsenic**, **copper**, **lead**, and **mercury**. Some prominent inorganic pesticides include Bordeaux mixture, a complex pesticide with several copper-based active ingredients, used as a **fungicide** for fruit and vegetable crops; and various arsenicals used as non-selective herbicides and **soil** sterilants and sometimes as insecticides.
- Organic pesticides, which are a chemically diverse group of chemicals. Some are produced naturally by certain plants, but the great majority of organic pesticides have been synthesized by chemists. Some prominent classes of organic pesticides are:
- Biological pesticides are bacteria, **fungi**, or viruses that are toxic to pests. One of the most widely used biological insecticide is a preparation manufactured from spores of the bacterium ***Bacillus thuringiensis***, or B.t. Because this insecticide has a relatively specific activity against leaf-eating lepidopteran pests and a few other insects such as blackflies and mosquitoes, its non-target effects are small.

The intended ecological effect of a pesticide application is to control a pest species, usually by reducing its abundance to an economically acceptable level. In a few situations, this objective can be attained without important non-target damage. However, whenever a pesticide is broadcast-sprayed over a field or forest, a wide variety of on-site,

non-target organisms are affected. In addition, some of the sprayed pesticide invariably drifts away from the intended site of deposition, and it deposits onto non-target organisms and ecosystems. The ecological importance of any damage caused to non-target, pesticide-sensitive organisms partly depends on their role in maintaining the integrity of their **ecosystem**. From human perspective, however, the importance of a non-target pesticide effect is also influenced by specific economic and esthetic considerations.

Some of the best known examples of ecological damage caused by pesticide use concern effects of DDT and other **chlorinated hydrocarbons** on predatory birds, marine mammals, and other wildlife. These chemicals accumulate to large concentrations in predatory birds, affecting their reproduction and sometimes killing adults. There have been high-profile, local and/or regional collapses of populations of **peregrine falcon** (*Falco peregrinus*), **bald eagle** (*Haliaeetus leucocephalus*), and other raptors, along with **brown pelican** (*Pelecanus occidentalis*), western grebe (*Aechmorphorus occidentalis*), and other waterbirds. It was the detrimental effects on birds and other wildlife, coupled with the discovery of a pervasive presence of various chlorinated **hydrocarbons** in human tissues, that led to the banning of DDT in most industrialized countries in the early 1970s. These same chemicals are, however, still manufactured and used in some tropical countries.

Some of the pesticides that replaced DDT and its relatives also cause damage to wildlife. For example, the commonly used agricultural insecticide carbofuran has killed thousands of waterfowl and other birds that feed in treated fields. Similarly, broadcast-spraying of the insecticides phosphamidon and fenitrothion to kill spruce budworm in infested forests in New Brunswick, Canada, has killed untold numbers of birds of many species.

These and other environmental effects of pesticide use are highly regrettable consequences of the broadcast-spraying of these toxic chemicals in order to cope with pest management problems. So far, similarly effective alternatives to most uses of pesticides have not been discovered, although this is a vigorously active field of research. Researchers are in the process of discovering pest-specific methods of control that cause little non-target damage and in developing methods of **integrated pest management**. So far, however, not all pest problems can be dealt with in these ways, and there will be continued reliance on pesticides to prevent human and domestic-animal diseases and to protect agricultural and forestry crops from weeds, diseases, and depredations caused by economically important pests. *See also* Agent Orange; Agricultural chemicals; Agricultural pollution; Algicide; Chlordane; Cholinesterase inhibitor; Diazinon; Environmental health; Federal Insecticide, Fungicide and Rodenticide Act (1947); Kepone; Methylmercury seed dressings; National Coalition Against the Misuse of Pesticides; Organochloride; Persistent compound; Pesticide Action Network; Pesticide residue; 2,4-D; 2,4,5-T

Pesticide Action Network

The **Pesticide** Action Network is an international coalition of more than 300 nongovernmental organizations (NGOs) that works to stop both pesticide misuse and the proliferation of pesticide use worldwide. The Pesticide Action Network North America Regional Center (PANNA) is the North American member.

The Pesticide Action Network serves as a clearinghouse to disseminate information to pesticide action groups and individuals in this country and abroad. It promotes research on and implementation of alternatives to pesticide use in agriculture, such as **integrated pest management** programs. With a library of 6,000 books, reports, articles, slides, and other materials, it sponsors a pesticide issues referral and information service.

Formerly called the Pesticide Education Action Project, which was founded in 1982, PANNA conducts the Dirty Dozen Campaign to "replace the most notorious pesticides with sustainable, ecologically sound alternatives." Various materials published by PANNA include brochures, pamphlets and books on United States pesticide problems and on global pesticide use. It publishes a quarterly newsletter, *Global Pesticide Campaigner*, and a bimonthly publication, *PANNA Outlook*.

The organization also publishes a number of books dealing with pesticides and **pest** control including *Problem Pesticides, Pesticide Problems: A Citizen's Action Guide to the UN Food and Agriculture Organization's (FAO) International Code of Conduct on the Distribution and Use of Pesticides*; *FAO Code: Missing Ingredients*; and *Breaking the Pesticide Habit: Alternatives to 12 Hazardous Pesticides*. While PANNA is not a membership organization for individuals outside of

Pesticides

Type	Examples	Characteristics	Type	Examples	Characteristics
Insecticides					
Inorganic chemicals	Mercury, lead, arsenic, copper sulfate	Highly toxic to many organisms, persistent, bioaccumulates	Plant products and synthetic analogs	Nicotine, rotenone, pyrethrum, allethrin, decamethrin, resmethrin, fenvalerate, permethrin, tetramethrin	Natural botanical products and synthetic analogs, fast acting, broad insecticide action, low toxicity to mammals, expensive
Organochlorines	DDT, methoxychlor, heptachlor, HCH, pentachloraphenol, chlordane, toxaphene, aldrin, endrin, dieldrin, lindane	Mostly neurotoxins, cheap, persistent, fast acting, easy to apply, broad spectrum, bioaccumulates, biomagnifies	*Fungicides*	Captan, maneb, zeneb, dinocap, folpet, pentachlorphenol, methyl bromide, carbon bisulfide, chlorothalonil (Bravo)	Most prevent fungal spore germination and stop plant diseases; among most widely used pesticides in United States.
Organophosphates	Parathion, malathion, diazinon, dichlorvos, phosdrin, disulfoton, TEPP, DDVP	More soluble, extremely toxic nerve poisons, fast acting, quickly degraded, toxic to many organisms, very dangerous to farm workers	*Fumigants*	Ethylene dibromide, dibromochloro-propane, carbon tetrachloride, carbon disulfide, methyl bromide	Used to kill nematodes, fungi, insects, and other pests in soil, grain, fruits; highly toxic, cause nerve damage, sterility, cancer, birth defects
Carbamates and urethanes	Carbaryl (Sevin), aldicarb, carbofuran, methomyl, Temik, mancozeb	Quickly degraded, do not bioaccumulate, toxic to broad spectrum of organisms, fast acting, very toxic to honey bees	*Herbicides*	2,4 D; 2,4,5 T; paraquat, dinoseb, diaquat, atrazine, Silvex, linuron	Block photosynthesis, act as hormones to disrupt plant growth and development, or kill soil micro-organisms essential for plant growth
Formamidines	Amitraz, chlordimeform (Fundal and Galecron)	Neurotoxins specific for certain stages of insect development, act synergistically with other insecticides			
Microbes	*Bacillus thuringensis*	Kills caterpillars			
	Bacillus popilliae	Kills beetles			
	Viral diseases	Attack a variety of moths and caterpillars			

Different types of pesticides. (McGraw-Hill Inc. Reproduced by permission.)

the member NGOs, it does offer subscriptions to its quarterly newsletter.

Pesticide residue

Chemical substances—pesticides and herbicides—that are used as weed and insect control on crops and animal feed always leave some kind of residue either on the surface or within the crop itself after treatment. The amounts of residue vary, but they do remain on the crop when ready for harvest and consumption.

While these **chemicals** are generally registered for use on food crops, it does not necessarily mean they are "safe." As part of its program to regulate the use of pesticides, **Environmental Protection Agency** (EPA) sets "tolerances" which are the maximum amount of pesticides that may remain in or on food and animal feed. Tolerances are set at levels that are supposed to ensure that the public (including infants and children) is protected from unreasonable health risks posed by eating foods that have been treated.

Tolerances are initially calculated by measuring the amount of **pesticide** that remains in or on a crop after it is treated with the pesticide at the proposed maximum allowable level. The EPA then calculates the possible risk posed by that proposed tolerance to determine if it is acceptable.

In calculating risk, the EPA estimates exposure based on the "theoretical maximum residue concentration" (TMRC) normally assuming three factors: that all of the crop is treated, that residues on the crop are all at the maximum level, and that all consumers eat a certain fixed percent of the commodity in their diet. This exposure calculation is then compared to an "allowable daily intake" (ADI) and calculated on the basis of the pesticide's inherent toxicity.

The ADI represents the level of exposure in animal tests at which there appears to be no significant toxicological

effects. If the residue level for that crop—the TMRC—exceeds the allowable daily intake, then the tolerance will not be granted as the residue level of the pesticide on that crop is presumed unsafe. On the other hand, if the residue level is lower than the ADI, then the tolerance would normally be approved. Exposure rates are based on assumptions regarding the amount of treated commodities that an "average" adult person, weighing 132 lb (60 kg), eating an "average" diet would consume.

To set tolerances that are protective of human health, the needs information about the anticipated amount of pesticide residues found on food, the toxic effects of these residues, and estimates of the types and amounts of foods that make up our diet. The **burden of proof** is on the manufacturer who has a vested interest in getting EPA approval. A pesticide manufacturer begins the tolerance-setting process by proposing a **tolerance level**, which is based on field trials reflecting the maximum residue that may occur as a result of the proposed use of the pesticide. The petitioner must provide food residue and toxicity studies to show that the proposed tolerance would not pose an unreasonable health risk.

The Federal Food, Drug, and Cosmetic Act (FFDCA) requires that the manufacturer of any substances apply to the EPA for a tolerance or maximum residue level to be allowed in or on food. Because of the way pesticide residues are defined and incorporated into the food additive provisions of the FFDCA, there are actually several kinds of tolerances, each subject to different decisional criteria. A given pesticide can thus have many tolerances, both for use on different crops and for any one crop. For example, for each crop for which it is registered, a pesticide may need a raw tolerance, a food additive tolerance, and an animal feed tolerance, each of which will be subject to particular decisional criteria.

The EPA sets tolerances on the basis of data the manufacturer is required to submit on the nature, level, and toxicity of a substance's residue. According to the EPA, one requirement is for the product chemistry data, which is information about the content of the pesticide products, including the concentration of the ingredients and any impurities. The EPA also requires information about how plants and animals metabolize (break down) pesticides to which they are exposed and whether residues of the metabolized pesticides are detectable in food or feed. Any products of pesticide **metabolism**, or "metabolites," that may be significantly toxic are considered along with the pesticide itself in setting tolerances.

The EPA also requires field experiments for pesticides and their metabolites for each crop or crop group for which a tolerance is requested. This includes each type of raw food derived from the crop. Manufacturers must also provide information on residues found in many processed foods (such as raisins), and in animal products if animals are exposed to pesticides directly through their feed.

A pesticide's potential for causing adverse health effects, such as **cancer**, **birth defects**, and other reproductive disorders, and adverse effects on the nervous system or other organs, is identified through a battery of tests. Tests are conducted for both short-term or "acute" toxicity and long-term or "chronic" toxicity. In several series of tests, laboratory animals are exposed to different doses of a pesticide and EPA scientists evaluate the tests to find the highest level of exposure that did not cause any effect. This level is called the "No Observed Effect Level" or NOEL.

Then, according to the EPA, the next step in the process is to estimate the amount of the pesticide to which the public may be exposed through the food supply. The EPA uses the Dietary Risk Evaluation System (DRES) to estimate the amount of the pesticide in the daily diet, which is based upon a national food consumption survey conducted by the **U.S. Department of Agriculture**. The USDA survey provides information about the diets of the overall American population and any number of subgroups, including several different ethnic groups, regional populations, and age groups such as infants and children.

Finally, for non-cancer risks, the EPA compares the estimated amount of pesticide in the daily diet to the Reference Dose. If the DRES analysis indicates that the dose consumed in the diet by the general public or key subgroups exceeds the Reference Dose, then generally the EPA will not approve the tolerance. For potential carcinogens, the EPA ordinarily will not approve the tolerance if the dietary analysis indicates that exposure will cause more than a negligible risk of cancer.

There have been serious problems in carrying out the law. Although the law requires a thorough tolerance review for chemical pesticides prior to registration for health and environmental impacts, the majority of pesticides currently on the market and in use today were registered before modern testing requirements were established. "Thus," according to a 1987 report published by the **National Research Council** Board on Agriculture, "many older pesticides do not have an adequate data base, as judged by current standards, particularly data about potential chronic health effects."

The 1972 amendments to the **Federal Insecticide, Fungicide and Rodenticide Act** (FIFRA) required a review—or registration—of all then-registered products according to contemporary standards. Originally, the EPA was to complete the review of all registered products within three years, but this process broke down completely. In 1978, amendments were added to FIFRA that authorized the EPA to group together individual substances by active ingredients for an initial "generic" review of similar chemicals in order

to identify data gaps and assessment needs. The amendments mandate that after this generic review, the EPA is to establish as "registration standard" for the active ingredient basis. Then, the EPA must wait for additional data in order to establish specific requirements for each substance's specific use on differing crops. (The EPA does not specifically address inert ingredients, although inert ingredients have been found to be just as potentially toxic as the active ingredients.)

The 1988 amendments extended the deadline for re-registration until 1997. To date, however, the EPA only has complete residue data on less than 25% of pesticides used on foods, and less than ten products, as yet, have been registered. Thus, the backlog of substances awaiting re-registration is on the order of some 16,000 to 20,000 compounds, including, according to the General Accounting Office, over 650 active ingredients. As a consequence, most of these untested chemicals temporarily retain their registration status under the former testing requirements.

Once tested in accordance with contemporary standards, many of the older pesticides are likely to be identified as carcinogenic. In fact, the **National Academy of Sciences** estimates that 25–33% of the pesticides to undergo re-registration procedures are likely to be found to be oncogenic. An oncogen causes tumors in laboratory animals and is considered potentially cancerous to humans. In general, such older pesticides, registered prior to 1972, have not been tested adequately for oncogenicity. For a substance to be used on a new crop, however, current data must be submitted in order to obtain a tolerance.

One way pesticide companies are able to completely skirt EPA regulations is to send pesticides that are suspended or banned in the United States to **Third World** countries. At least 25% of American pesticide exports are products that are banned, heavily restricted or have never been registered for use in the United States. Hazardous pesticide exports are a major source of **pollution** in Third World countries where lack of regulation, illiteracy, and repressive working conditions can turn even a "safe" pesticide into a deadly weapon for the field workers. These pesticides are returned to the United States, unexamined, as residues in the imported food American consumers eat.

Pet trade

Pets are part of human cultures all around the world. We keep animals to admire their beauty or to enjoy their companionship or devotion. The pet trade is big business throughout the world but with its positive aspects, there are distinct negative ones as well. As with any commodity, economics dictates that the rarer an item is, the more valuable it becomes in the market place. Many **rare species** thus become quite valuable to wealthy collectors, who are willing to pay exorbitant prices to black market dealers for certain species—even though they are protected by international treaties and laws.

Because these illegal pets must be smuggled into the market arenas, concealment almost always requires physical abuse of the animals. This may be in the form of constrictive bindings, overcrowded or confined spaces, exposure to extreme heat, or lack of oxygen due to these restrictions. Such treatment results in the death of many individuals during transit, with **mortality** that often approaches 80–90%. Therefore, collectors and smugglers must over-collect specimens in order to ensure the delivery of a sufficient quantity to realize a profit. Two groups, monkeys and **parrots**, have been the recipients of the bulk of this treatment. Due to their popularity as pets, there is a lucrative business in their illegal trade, and because the rarer **species** bring a higher price, these practices further threaten **extinction** of certain species.

This problem extends beyond the black market trade in birds and mammals. Other animal groups, as well as the legal pet trade, are also involved. Exotic reptiles, snakes and lizards in particular, are a target group. Legitimate pet dealers get involved in this problem when they, often unknowingly, purchase pets that were illegally caught or smuggled.

The **aquarium trade** has also faced illegal collecting. Over-collecting and poor handling of specimens during shipment have been problems in the freshwater segment of this business, but recent years have produced rampant abuses in the marine aquarium trade. Advances in technology over the past twenty years have made marine aquaria more accessible to the general public, and the sheer beauty of the brilliant, often neon-like, colors of many of the **coral reef** fish has fascinated a new breed of aquarists.

The main problems here still include the removal of large numbers of specimens of localized populations of rare or low density species and their illegal trade. Now, new and profound problems exist in the capture of these marine

creatures: the total destruction of their **habitat** and the killing of unwanted, non-commercial species. Although legitimate collecting of marine fish is done with nets, it is estimated that during the 1980s about 80% of specimens for the marine aquarium trade were collected by using poison. Since most of the **target species** use coral reefs as hiding places, collectors use a squeeze bottle filled with sodium cyanide to force the fish out into the open water. The stunned, gasping fish are thus more easily caught, but the section of coral reef sprayed with poison, and the animals that did not escape, are now dead. Lingering effects of the poison and abusive shipping practices lead to mortality rates of 60–80% for these pets.

Public awareness and some governmental regulations have eased some of the abuses of these animals, but the illegal pet trade is still a profitable business. As long as people are willing to purchase rare species, the illegal pet trade will threaten the very species the collectors hold in high esteem. *See also* Endangered Species Act; Overhunting; Parrots and parakeets; Poaching; Wildlife management

Roger Tory Peterson (1908 – 1996)

American ornithologist

A small book, tucked away in innumerable back-packs and car pockets, ever ready to hand for perhaps the majority of birders in the United States, is quite likely to be Roger Tory Peterson's *A Field Guide to the Birds*, first published in 1934, revised and reissued several times, and still a must-have for many bird-watchers, serious or otherwise. In 1941 it was joined by a companion volume, *A Field Guide to Western Birds*. Together, the two guides (the first rejected by four publishers before Houghton Mifflin finally accepted it) have sold on the order of seven million copies by 1997. The critic William Zinser suggested that Peterson's *Field Guide* was "the single most revolutionary development in American birding." He was the first to introduce simplified, comparative drawings and to point out key field marks (distinguishing characteristics) that help identification in the field. Later critics judged Peterson harshly for his last revision of the *Guide* as "not knowing much about contemporary identification skills." But the revolutionary importance of the *Guides* lies in the number of people they have "turned on" to birds and to birding; they still sell, and are still used by birders at every level.

The man who has been called the modern successor to John James Audubon was born in Jamestown, New York, of a Swedish immigrant father and a German immigrant mother. Reportedly a loner, a boy considered strange by other children, Peterson came out of his shell when one of his teachers started a Junior Audubon Club. Birds became a passion for the eleven-year old, and he sought a job as a newspaper delivery boy so that he could buy a camera to photograph birds. Some seven decades later, he was still making pictures of birds. The prescient caption under his photograph in his high school yearbook read "Woods! Birds! Flowers! Here are the makings of a great naturalist."

Peterson studied art rather than ornithology, and he considered himself first a painter, then a writer, and only third a naturalist. Yet such was his reputation and standing among people interested in natural history that the *New York Times* could announce his death as that of "the best-known ornithologist of the twentieth century." Because his work reached so many people, because it helped them become involved in knowing more about the world around them, and because it inspired them to actually get out in the field and get involved, Peterson might even deserve *Sports Afield's* label of "the twentieth century's most influential naturalist." Academically trained or not, he spent his lifetime doing ornithology, i.e., studying birds, and in getting other people to join in that passion. His guides provided clear access to bird identification, even for the most rank amateur. Along with his many awards for art, he was also honored as a Fellow in the American Association for the Advancement of Science, and was bestowed with the Linné gold medal of the Royal Swedish Academy of Sciences.

After art school, he taught at a boys' school in Massachusetts. The success of the first field guide allowed him to return to New York to a position as an educational specialist and art editor for *Audubon Magazine*. He remained associated with the **National Audubon Society** for the rest of his professional life, serving in various capacities as artist, writer, secretary, and two different terms as director.

His passion for **nature** centered on birds, certainly, but he also was enthusiastic for all of the natural world,

worked on many fronts to protect its diversity, and became an advocate for and teacher about managing the **environment** wisely. For example, he and his wife shared a love of flowers, and created and maintained butterfly gardens; one of his best known field guides is for wildflowers. All told, he published almost 50 books, including his edition of *Audubon's Birds of America*, and wrote many articles on birds as well as on other topics in **conservation** and management of gardens and wildlands.

As stated in a *New York Times* editorial, Peterson did indeed become "a great naturalist and more. He was one of the pioneers in teaching twentieth-century Americans to walk more gently on their land."

Petrochemical

Petroleum is probably best known as a source for many important fuels, such as **gasoline**, kerosene, acetylene, and **natural gas**. However, many of the organic compounds that make up the complex mixture known as petroleum have another use. They are raw materials used in the production of a host synthetic products. These **chemicals** are known as petrochemicals. To a large extent, these petrochemicals are **hydrocarbons**. Some of these petrochemicals and the products into which they are made include ethylene (**plastics**, synthetic fibers, and anti-freeze), **benzene** (synthetic **rubber**, latex paints and paper coatings), propylene (drugs and **detergents**), and phenol (adhesives, perfumes, flavorings, and pesticides). *See also* Fossil fuels; Synthetic fuels; Volatile organic compound

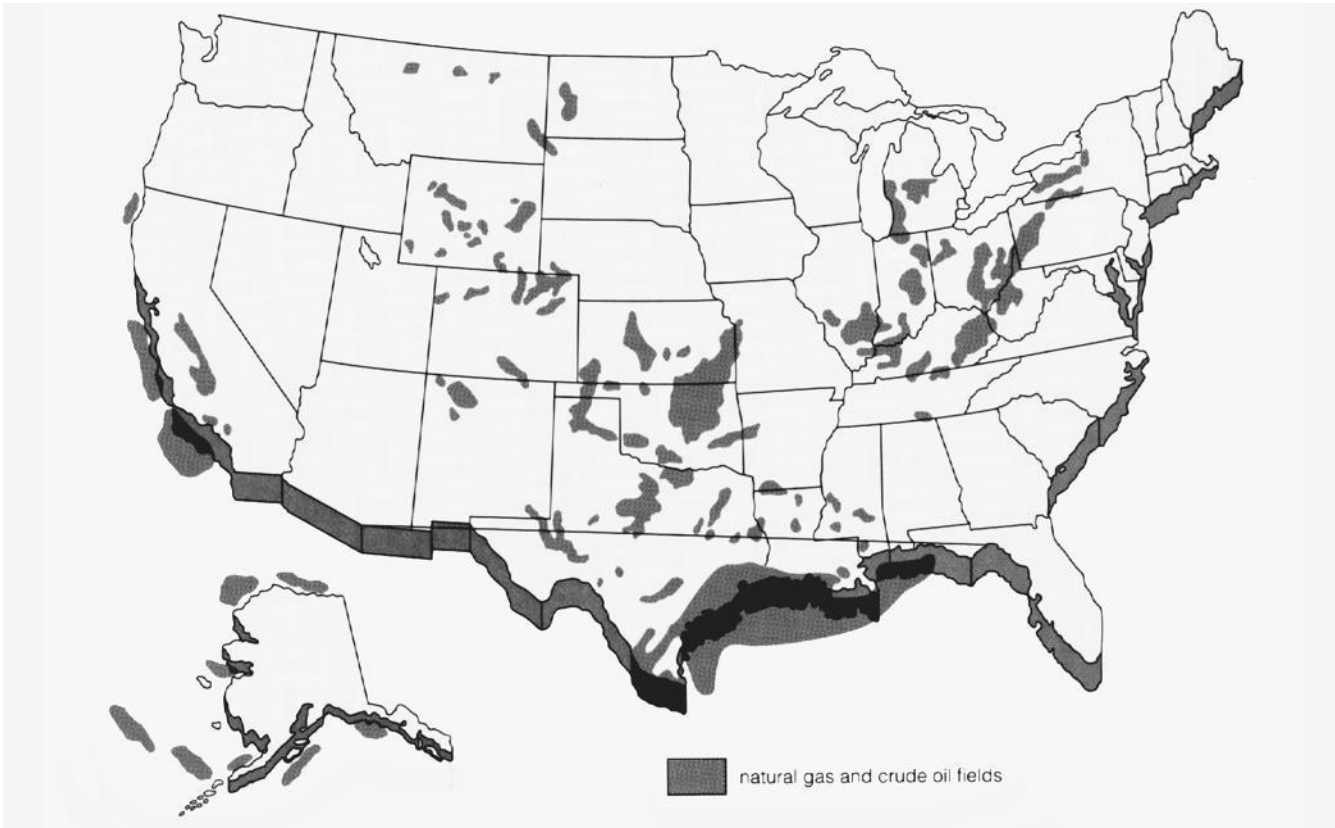
Petroleum

Petroleum is a complex mixture of solid, liquid, and gaseous **hydrocarbons** normally found a few miles beneath the earth's surface. It, along with **coal** and **natural gas**, is one of the **fossil fuels**. That name comes from the most common scientific theory that these three materials were formed between 10 and 20 million years ago as a product of the decay of plants and animals. Petroleum is sometimes called crude oil or, simply, oil, although some authorities give slightly different means to these terms.

Most commonly, petroleum and natural gas occur together under dome-shaped layers of rock. When **wells** are drilled into such domes, gas pressure forces petroleum up into the well, producing the "gushers" that are typical of successful new wells.

Petroleum has been known to and used by humans for thousands of years. Collecting the liquid that seeped to the surface, the Egyptians, Babylonians, and Native American Indians used petroleum for waterproofing, embalming, caulking ships, warpaint, and medicine. The first successful oil well in the United States was drilled in 1859 by "Colonel" Edwin Drake.

The number and variety of compounds found in petroleum are large, and its composition varies significantly from location to location. Petroleum from Pennsylvania tends to have a high proportion of aliphatic (open-chain) hydrocarbons, those from the West contain more aromatic (benzene-based) hydrocarbons, and those from the Midwest contain a more even mix of the two.



The most common impurities (non-hydrocarbon compounds) in petroleum are compounds of sulfur and **nitrogen**. The percentage of sulfur in a sample of petroleum determines its status as "sweet" (low-sulfur) or "sour" (high-sulfur) crude oil. The emphasis on sulfur derives from the fact that one of the most undesirable products of the **combustion** of petroleum is **sulfur dioxide**. Oil with low sulfur is, therefore, more desirable than that with high sulfur.

The complex mix of compounds that make up petroleum results in its having relatively few important uses in its natural state. It becomes an important product only when some method is used to separate the native liquid into its component parts. The fractional distillation of petroleum results in the production of portions known as petroleum ether, **gasoline**, kerosene, heating oil, lubricating oil, and a semi-solid residue that includes paraffin, pitch, and tar. Each of these fractions can then be utilized directly or subdivided even further.

Few naturally occurring materials have as many environmental effects as does petroleum. During its removal from the earth, it may escape from wells and contaminate **groundwater**. The combustion of some of its most important components, gasoline, kerosene and fuel oil results in the release of **carbon dioxide**, **carbon monoxide**, **carbon**, sulfur dioxide, and **nitrogen oxides**, all compounds that contribute to **air pollution**, global warming, or other environmental problems.

In recent decades, petroleum has found another major use: in the production of petrochemicals. The compounds found in oil are now important starting materials in the manufacturing of a nearly limitless number of synthetic products. The manufacture, use and disposal of these **petrochemical** products contributes to additional environmental prob-

Natural gas and oil deposits in the United States. (Council on Environmental Quality.)

lems such as **hazardous waste** disposal and **solid waste** accumulation. *See also* Alternative fuels; Decomposition; Emission standards; Greenhouse effect; Groundwater pollution; Oil drilling; Oil spills

Pfiesteria

Pfiesteria piscicida (fee-STEER-ee-uh pis-kuh-SEED-uh) is a microscopic, polymorphic organism that belongs to a group of single-celled, free-swimming **phytoplankton** called dinoflagellates. Although many phytoplankton photosynthesize to generate the energy they need to survive, *Pfiesteria* does not—it is more animal-like in that it consumes other organisms such as bacteria and algae. It can transform in and out of the following stages within a matter of minutes: flagellated, amoeboid, and cyst. In the flagellated stage *Pfiesteria* is powered by two tiny flagella that resemble tails. The cyst stage lies dormant in the bottom sediments of estuaries and rivers.

Two **species** are known to release **toxins** that are harmful to aquatic and human life: *Pfiesteria piscicida* and *Pfiesteria shumwayae*.

When it was discovered in 1988, *Pfiesteria* was declared to be a new family (Pfiesteriaceae), genus (*Pfiesteria*), and species (*piscicida*), in the order Dinamoebales. It was named in honor of Dr. Lois Pfiester, an internationally respected

researcher of dinoflagellates. Since its discovery, it has been identified in mud cores from the bottom of **Chesapeake Bay** that are at least 3,000 years old.

Depending on its stage, *Pfiesteria piscicida*, the most studied *Pfiesteria* species, ranges in size from about 5–450 microns in diameter. It is typically found in the bottom sediments and water of **brackish** tidal rivers and estuaries, primarily along the eastern seaboard of the United States.

Pfiesteria is a remarkably hardy organism that can survive over a wide range of temperatures and water salinities. For most of its life cycle *Pfiesteria* is a nontoxic predator, feeding on bacteria, algae, and other small organisms. When schools of fish are present, *Pfiesteria* occasionally responds with a quick release of **biotoxins** into the water. These **chemicals** stun or kill the fish, which allow the *Pfiesteria* to feed on the injured skin, blood, and dying tissue.

These toxic episodes last for several hours before dissipating, sometimes resulting in large-scale **fish kills**, many of which plagued the Atlantic coastline in the late 1980s and 1990s. Fish kills attributed to *Pfiesteria* occurred in estuaries in the Albemarle–Pamlico estuarine system in North Carolina, Chesapeake Bay tributaries in Virginia, the Chicamacomico, Pokomoke, and Manokin Rivers and King's Creek in Maryland, and Indian River in Delaware. *Pfiesteria* has been identified as far north as Long Island, New York, and as far west as the southern tip of Texas. It may also occur in Pacific waters along the California–Oregon–Washington coastline, but has not yet been identified because these waters have not been sampled.

Although *Pfiesteria* is technically not an algae, it's fish kills are usually included under the category of harmful algal blooms (HABs). This is because *Pfiesteria* shares many physiological and toxicological characteristics with the various algae species that cause algal blooms (red or brown tides), some of which are toxic to aquatic life.

Toxic strains of *Pfisteria* have been identified along European, Scandinavian, New Zealand, and **Australia** coastlines. It likely occurs in other international waters that have not been tested for its presence. As the technology of detection improves, it is highly probable the global distribution of *Pfiesteria* will become better defined. However, the United States is the only country in the world that has experienced the serious deleterious effects of its toxins on aquatic life and human health.

When *Pfiesteria* detects fish oils or excretions in the water from a large school of fish, a biological toxic response may be triggered. The organisms change from the cyst stage (excystment) into the predator flagellate or ameoboid stages, which then release potent toxins into the water.

The toxins penetrate the skin of the fish, creating bleeding ulcers. The fish become lethargic or die. The skin becomes so damaged that the fish cannot maintain their internal salt balance. The *Pfiesteria* organisms feed on the dead skin tissue, blood, and other fish fluids leaking into the water. Within several hours *Pfiesteria* transforms back to the cyst stage (encystment) and lays dormant in the bottom sediments. Fish kills usually occur in warmest times of the year and when the **dissolved oxygen** content of the water is low.

There has been a global increase in toxic and harmful algae blooms in the late twentieth century, including *Pfiesteria*. Modern technology increasingly allows for the rapid identification of the species causing the bloom or the fish kill. *Pfiesteria* attacks are becoming a growing problem because they have a negative impact on **commercial fishing**, **recreation**, and human health along the eastern seaboard.

Toxins can be present in the water or aerosolize into the air. Toxic episodes and fish kills close down sections of coastline, which impact the fish and shellfish industries. If fish aren't killed directly by *Pfiesteria*, they are seriously weakened, which makes them susceptible to other predators or bacterial and fungal infections. Humans can suffer serious health problems from coming into contact with, or inhaling, these biotoxins. Effects to humans and aquatic life persist for six to eight weeks after the bloom disappears.

Two kinds of toxins have been discovered to date: a fat-soluble toxin that blisters skin and a water-soluble toxin that affects the nervous system. Injection of *Pfiesteria* toxin has induced significant learning problems in laboratory rats. Symptoms in humans consist of lethargy, sores and rashes, eye sensitivity, headaches, blurred vision, gastrointestinal distress, nausea, memory loss, kidney and liver problems, shortness of breath, and fibromyalgia-like symptoms. Symptoms can recur for up to eight years after exposure. This condition, sometimes referred to as possible estuary-associated syndrome (PEAS) can be developed from exposure to *Pfiesteria* biotoxins, even if there is no evidence of fish kills or fish disease in the water.

Identifying a fish kill as being *Pfiesteria*-related (and taking subsequent actions, such as closing shorelines and issuing fish consumption warnings) can be difficult because *Pfiesteria* has 24 recognized morphological shapes at different growth stages. Scientists use light microscopes, bioassays, scanning electron microscopes, or polymerase **chain reaction** (PCR) methods to establish positive identifications.

An unanswered question remains: Are fish from areas that have experienced *Pfiesteria* outbreaks safe to consume? This may have significant impact to the fishing industry. So far research indicates that no person has become ill from eating fish or shellfish that have been exposed to *Pfiesteria*—the data, however, are limited. Most experts recommend to err on the side of caution: If an area has been closed because of a *Pfiesteria* outbreak, do not catch or consume fish from

that area or swim or waterski in those waters for at least eight weeks after the outbreak.

Data suggest that *Pfiesteria* has a fairly wide global distribution, but only creates health problems under certain conditions, which seem to be best demonstrated in the coastal estuaries of the eastern and southern United States.

Research at North Carolina State University's Center of Applied Aquatic Ecology shows that *Pfiesteria* is stimulated by organic or inorganic **nitrogen** and **phosphorus** in the water—two key components of **fertilizer**. **Carbon** may also be a trigger substance. It has been documented that *Pfiesteria* outbreaks occur in areas that are downstream from septic tanks, sewage-plant discharges, agricultural waste such as excrement from cattle, swine, and poultry, and agricultural or landscaping chemical **runoff**. When these nutrients accumulate in slow-moving or stagnant sections of estuaries and mix with the incoming tidal water, *Pfiesteria* can become more active and toxic. Other stimulators may be airborne pollutants that settle in the water. An abundance of fish is also required. As yet it has not been determined if the **nutrient loading** stimulates the growth of the algae on which *Pfiesteria* feeds, or if directly stimulates *Pfiesteria*.

Federal organizations such as the U.S. **Environmental Protection Agency** (EPA), U.S.Department of Agriculture, **U.S. Department of the Interior**, **National Oceanic and Atmospheric Administration**, Centers for Disease Control and Prevention(CDC), and the **National Institute of Environmental Health Sciences**, state departments of health or **natural resources**, and several prominent university research centers are continuing research into the life cycles of *Pfiesteria* and other *Pfiesteria*-like organisms, their nutritional ecologies, and the trigger mechanisms that result in toxic episodes.

One major areas of study focuses on integrating management approaches with new emerging technologies. This collaborative effort between risk managers, universities, federal agencies, and users—commercial and recreational fishermen, Native peoples, and other water users—will lead toward a systematic approach to managing the risk for exposure to *Pfiesteria* biotoxins. The ultimate goal is to develop an accurate model of prediction—what conditions will result in toxic *Pfiesteria*/algal blooms? Knowing these factors may reduce or eliminate the need to close down sections of coastline and interrupt commercial fishing operations.

Researchers are also attempting to purify and study *Pfiesteria* biotoxins. When the actual toxin can be identified, it will be much easier to determine if fish kill/disease episodes are related to *Pfiesteria* attacks. Once the chemical signature of the toxin is identified, methods can be developed to test humans for exposure. Antitoxins or related drugs may also be developed. It is also possible that, when consumed or injected in prescribed dosages under certain conditions, *Pfiesteria* toxins may be useful medicines that reduce or alleviate other health conditions in humans.

PFOS

see **Perfluorooctane sulfonate**

pH

A measure of the acidity or alkalinity of a solution based on its **hydrogen ion** (H^+) concentration. The pH of a solution is the negative logarithm (base 10) of its H^+ concentration. Since the scale is logarithmic, there is a tenfold difference in hydrogen ion concentration for each pH unit. The pH scale ranges from 0 to 14 with 7 indicating neutrality ((H^+) = (OH^-)). Values above 7 indicate progressively greater alkalinity, while values below 7 indicate progressively increasing acidity. *See also* Acid and base; Buffer

pH scale. (McGraw-Hill Inc. Reproduced by permission.)

Phosphates

Phosphorus is essential to the growth of biological organisms, including both their metabolic and photosynthetic processes. Phosphorus occurs naturally in bodies of water mainly in the form of phosphate (i.e., a compound of phosphorus and oxygen). Addition of phosphates through the activities of humans can accelerate the eutrophication process of **nutrient** enrichment that results in accelerated ecological aging of lakes and streams. Phosphorus, especially in inland waters, is often the nutrient that limits growth of aquatic plants. Thus when it is added to a body of water, it may result in increased plant growth that gradually fills in the lake. Critical levels of phosphorus in water, above which eutrophication is likely to be triggered, are approximately 0.03 mg/l of dissolved phosphorus and 0.1 mg/l of total phosphorus. The **discharge** of raw or treated **wastewater**, agricultural **drainage**, or certain industrial wastes that contain phosphates to a surface water body may result in a highly eutrophic state, in which the growth of photosynthetic aquatic micro- and macroorganisms are stimulated to nuisance levels. Aquatic plants and mats of algal scum may cover the surface of the water. As these algal mats and aquatic plants die, they sink to the bottom, where their **decomposition** by **microorganisms** uses most of the oxygen dissolved in the water. The decrease in oxygen severely inhibits the growth of many aquatic organisms, especially more desirable fish (e.g., recreational catch fish such as trout) and in extreme cases may lead to massive **fish kills**. Excessive input of phosphorus can change clear, oxygen-rich, good-tasting water into cloudy, oxygen-poor, foul smelling, and possibly toxic water. Therefore, control of the amount of phosphates entering surface waters from domestic and industrial waste discharges, natural **runoff**, and **erosion** may be required to prevent eutrophication.

Rocks may contain phosphates; those with calcium phosphate upon heat treatment with sulfuric **acid** serve as a source of fertilizers. Phosphates, in addition to those found in fertilizers, are also present in such consumer products as detergent, baking powders, toothpastes, cured meats, evaporated milk, soft drinks, processed cheeses, pharmaceuticals, and water softeners. Phosphates are classified as orthophosphates (PO_4^{-3}, HPO_4^{-2}, $H_2PO_4^{-}$, and H_3PO_4); condensed phosphates, or polyphosphates, which are molecules with two or more phosphorus atoms, oxygen atoms and in some cases, **hydrogen** atoms, combined in a complex molecule; and organically-bound phosphates.

Orthophosphates in an aqueous solution can be used for biological **metabolism** without further breakdown. Orthophosphates applied to agricultural or residential cultivated land as fertilizers may be carried into surface waters with **storm runoff** and melting snow.

Polyphosphates can be added to water when it is used for laundering or cleaning, for polyphosphates are present as builders of some commercial cleaning preparations for the public health sector. Massive algal blooms in lakes and floating foam on rivers aroused alarm in the United States in the 1970s. After it was shown that phosphates from **detergents** were a key factor, legislation banning the use

of phosphates in home laundry detergents was passed in many areas. Phosphate legislation usually includes exemptions for products such as hard-surface cleaner and automatic dishwashing detergents used in the public health sector. Polyphosphates may also be added to water supplies during culinary **water treatment** and during treatment of boiler water. Polyphosphates slowly undergo hydrolysis in aqueous solutions and are converted to the orthophosphate forms.

Organic phosphates are formed primarily by biological processes. They enter sewage water through body wastes and food residues. They may also be formed from orthophosphates in biological treatment processes and by receiving water organisms. Like polyphosphates, they are biologically transformed back to orthophosphates.

One means of surface water protection from phosphorus addition in both domestic and industrial wastewaters is the use of **phosphorus removal** processes in wastewater treatment. Phosphates are typically present in raw wastewaters at concentrations near 10 mg/l as P. During wastewater treatment, about 10-30% of the phosphates in raw wastewater is utilized during secondary biological treatment for microbial cell synthesis and energy transport. Additional removal is required to achieve low **effluent** concentration levels from the wastewater treatment process. Effluent limits usually range from 0.1-2 mg/l as P, with many established at 1.0 mg/l. Removal processes for phosphates from wastewaters utilize incorporation into suspended solids and the subsequent removal of those solids. Phosphates can be incorporated into chemical precipitates that are insoluble or of low solubility or into biological solids, (e.g, microorganisms).

Chemical precipitation is accomplished by the addition of metal salts or lime, with polymers often used as flocculant aids. The precipitation of phosphates from wastewater can occur during different phases within the wastewater treatment process. Pre-precipitation, where the **chemicals** are added to raw wastewater in primary **sedimentation** facilities, removes the precipitated phosphates with the primary **sludge**. In co-precipitation, the chemicals are added during secondary treatment to the effluent from the primary sedimentation facilities; to the mixed liquor in the activated-sludge process; or to the effluent from a biological treatment process before secondary sedimentation. They are removed with the waste biological sludge. In post-precipitation, the chemicals are added to the effluent from secondary sedimentation facilities and are removed in separate sedimentation facilities or in effluent **filters**.

The most commonly used metal salts are ferric chloride and **aluminum** sulfate (alum), which combine with phosphate to form the precipitates aluminum phosphate and iron phosphate, with one mole of iron or aluminum precipitating one mole of phosphate. However, because of competing reactions and the effects of alkalinity, **pH**, trace elements, and ligands found in wastewater, appropriate dosages are established on the basis of bench-scale or full-scale testing. Less commonly used metal salts are ferrous sulfate and ferrous chloride, which are available as by-products of steel production operations. Because polyphosphates and organic phosphorus are less easily removed than orthophosphates, adding metal salts after secondary treatment, where organic phosphorus and polyphosphates are transformed into orthophosphates, usually results in the best control.

Lime $(CaOH)_2$ is used less frequently because of the larger amounts of sludge produced as compared with the use of metal salts. Also, operating and maintenance problems are associated with the handling, storage, and feeding of lime. As lime is added to water, it reacts with natural bicarbonate alkalinity to precipitate $CaCO_3$. As the pH of the wastewater increases beyond about 10, excess calcium ions react with phosphates to precipitate hydroxylapatite, $Ca_{10}(PO_4)_6(OH)_2$. The amount of lime required will be independent of the amount of phosphate present and will depend primarily on the alkalinity of the wastewater and the degree of phosphate removal required. The pH of the wastewater must be adjusted by recarbonation with **carbon dioxide** (CO_2) before subsequent treatment or disposal. Lime can be added to primary sedimentation tanks or following secondary treatment.

Biological phosphate removal is accomplished by sequencing and producing appropriate environmental conditions in a reactor system in which microorganisms absorb and store phosphorus. The *Acinetobacter* bacteria are one of the primary microorganisms responsible for phosphorus uptake. The sludge containing the microorganisms with the excess phosphorus can either be wasted or removed and treated in a side stream to release the excess phosphate, which can then be treated with chemical precipitation processes. Wasted sludge, if it has a relatively high phosphorus content (3-5%), may have **fertilizer** value.

In natural treatment systems for wastewater, which include managed land-farms, landscape **irrigation** sites, **groundwater** recharge sites, and constructed **wetlands**, phosphates are removed by **sorption** with **clay minerals** in the **soil** matrix and by chemical precipitation. Sorbed phosphates are held tightly and are generally resistant to **leaching** until the soil sorptive capacity for phosphates becomes saturated. Chemical precipitation with calcium (in soils with neutral or alkaline pH) or with iron or aluminum (at acid pH) occurs at a slower rate than sorption, but is also an important removal mechanism. The degree of phosphorus removal in a natural treatment system depends on the degree of wastewater contact with the soil matrix.

Transport of phosphates into surface waters from nonpoint sources is controlled by practices that minimize soil erosion and runoff water. Phosphate losses from a **water-**

shed can be increased by a number of human activities, including timber harvest, intensive livestock grazing, soil tillage, and soil application of animal manures and phosphate-containing fertilizers. Since most soils, except for very sandy soils or soils with high levels of organic matter, retain phosphates through sorption and precipitation, techniques that prevent soil transport will also prevent transport of phosphates. Control of runoff water is required to prevent dissolved phosphates from entering rivers and lakes.

Phosphorus

An important chemical element, which has the atomic number 15 and atomic weight 30.9738. Phosphorus forms the basis of a large number of compounds, by far the most environmentally important of which are **phosphates**. All plants and animals need phosphates for growth and function, and in many natural waters the production of algae and higher plants is limited by the low natural levels of phosphorus. As the amount of available phosphorus in an aquatic **environment** increases, plant and algal growth can increase dramatically leading to eutrophication. In the past, one of the major contributors to phosphorus **pollution** was household **detergents** containing phosphates. These substances have now been banned from these products. Other contributors to phosphorus pollution are **sewage treatment** plants and **runoff** from cattle **feedlots**. (Animal feces contain significant amounts of phosphorus.) **Erosion** of farmland treated with phosphorus fertilizers or animal manure also contributes to eutrophication and **water pollution**. *See also* Cultural eutrophication

Phosphorus removal

Phosphorus (usually in the form of phosphate, PO^{3-}_4) is a normal part of the **environment**. It occurs in the form of phosphate-containing rocks and as the excretory and decay products of plants and animals. Human contributions to the phosphorus cycle result primarily from the use of phosphorus-containing **detergents** and fertilizers.

The increased load of phosphorus in the environment as a result of human activities has been a matter of concern for more than four decades. The primary issue has been to what extent additional phosphorus has contributed to the eutrophication of lakes, ponds, and other bodies of water. Scientists have long recognized that increasing levels of phosphorus are associated with eutrophication. But the evidence for a direct cause and effect relationship is not entirely clear. Eutrophication is a complex process involving **nitrogen** and **carbon**, as well as phosphorus. The role of each **nutrient** and the interaction among them is still not entirely clear.

In any case, environmental engineers have long explored methods for the removal of phosphorus from **wastewater** in order to reduce possible eutrophication effects. Primary and secondary treatment techniques are relatively inefficient in removing phosphorus with only about ten percent extracted from raw wastewater in each step. Thus, special procedures during the tertiary treatment stage are needed to remove the remaining phosphorus.

Two methods are generally available: biological and chemical. Bacteria formed in the **activated sludge** produced during secondary treatment have an unusually high tendency to adsorb phosphorus. If these bacteria are used in a tertiary treatment stage, therefore, they are very efficient in removing phosphorus from wastewater. The **sludge** produced by this bacterial action is rich in phosphorus and can be separated from the wastewater leaving water with a concentration of phosphorus only about five percent that of its original level.

The more popular method of phosphorus removal is chemical. A compound is selected that will react with phosphate in wastewater, forming an insoluble product that can then be filtered off. The two most common substances used for this process are alum, **aluminum** sulfate [$Al_2(SO_4)_3$] and lime, or calcium hydroxide [$Ca(OH)_2$]. An alum treatment works in two different ways. Some aluminum sulfate reacts directly with phosphate in the waste water to form insoluble aluminum phosphate. At the same time, the aluminum **ion** hydrolyzes in water to form a thick, gelatinous precipitate of aluminum hydroxide that carries phosphate with it as it settles out of solution.

The addition of lime to wastewater results in the formation of another insoluble product, calcium hydroxyapatite, which also settles out of solution.

By determining the concentration of phosphorus in wastewater, these chemical treatments can be used very precisely. Exactly enough alum or lime can be added to precipitate out the phosphate in the water. Such treatments are normally effective in removing about 95 percent of all phosphorus originally present in a sample of wastewater.

Photic zone

The surface waters of an ocean or lake that receive sufficient solar radiation to support **photosynthesis**, (i.e. the growth of vascular plants and **phytoplankton**). When sunlight falls on the surface of a lake or ocean, a large part of the light is reflected, scattered, or absorbed. Some light penetrates the water, but its intensity decreases quite rapidly with depth. The photic zone can be up to 328 ft (100 m) deep, and, typically, its limit is reached when the light intensity falls below one percent of the incident radiation.

Photochemical reaction

Photochemical reactions are driven by light or near-visible electromagnetic radiation. In general, incoming units of energy, known as photons, excite effected molecules, raising their energy to a point where they can undergo reactions that would normally be exceedingly difficult. The process is distinguished from thermal reactions, which take place with molecules in their normal energy states. Under sunlit conditions, photochemical processes can generate small amounts of extremely reactive molecules which initiate important chemical reaction sequences.

To initiate a photochemical reaction, two requirements need to be met. First, the photon must have enough energy to initiate the photochemical reaction in the molecule. Second, the compound must be colored, in order to be able to react with visible or near-visible photon radiation.

In **environmental chemistry**, photochemical reactions are of considerable importance to the trace chemistry of the **atmosphere**. The Los Angeles **photochemical smog** is an example of a system of photochemical reactions. Perhaps one of the most important reactions in this system is the photochemically driven conversion of **nitrogen** dioxide, a major component of **automobile** exhaust, to nitric oxide and an atom of oxygen, which usually occurs in pairs in the air. The oxygen atom subsequently attaches to an oxygen molecule to form the secondary pollutant, **ozone**. Photochemically initiated reactions are also responsible for generating the all important hydroxyl radical, a key intermediate in the trace chemistry of the lower atmosphere.

Photochemical reactions are also important in natural waters. Here they may be responsible for enhancing the reaction rate of organic compounds or changing the oxidation state of metallic ions in solution. However, some of these compounds are not colored, and are unable to absorb light. In such cases reactions may be mediated by photosensitizers, compounds capable of being energized by absorbed light which then pass the energy onto other molecules. Seawater appears to contain natural photosensitizers, perhaps in the form of fulvic **acid** or chlorophyll derivatives. Photosensitizers activated by sunlight can react with organic compounds or **dissolved oxygen** to produce the reactive singlet-oxygen, which can react rapidly with many seawater compounds.

Photochemical reactions also occur in solids. Since solids often lack the transparency required for the light to penetrate the surface, reactions are usually limited to the surface, where incoming photons initiate reactions in the top-most molecules. There is also some evidence that, under extremely bright **desert** sunlight, traces of nitrogen and water absorbed on titanium and zinc oxides can be photochemically converted to ammonia. Such processes are no doubt also important on planetary surfaces. *See also* Air pollution; Air quality; Emission; Los Angeles Basin

Photochemical smog

A form of **smog** that characterizes polluted atmospheres where high concentrations of **nitrogen oxides** and volatile organic compounds--often from gas-driven automobiles--mixed with sunlight promote a series of photochemical reactions that lead to the formation of **ozone** and a range of oxidized and nitrated organic compounds. The smog turns brownish in color and lowers **visibility** towards the middle of the day as sunlight becomes intense. The smog also causes eye irritation and a range of less distinct short- and long-term health effects. Photochemical smog, though typified by the **atmosphere** of the **Los Angeles Basin**, is increasingly found in cities all over the world where volatile fuels are used.

Photodegradable plastic

Plastics are clearly one of the great chemical inventions of all time. It would probably be impossible to list all the ways

in which plastics are used in everyday life. Suffice to say that, in the early 1990s, more than 60 billion pounds (27 billion kg) of plastics were produced in the United States alone each year.

For their many advantages, plastics also create some serious environmental problems. About one third, 20 billion pounds (9 billion kg), of all plastics now produced are used for short-term purposes, such as shopping bags and wrapping material. These plastics are used once, briefly, and then discarded.

Current estimates are that plastic materials make up about 7 percent by weight and 18 percent by volume of all municipal wastes. Since most plastics do not degrade naturally, they will continue to be a part of the nation's (and the world's) **solid waste** problem for decades.

One solution to the accumulation of plastics is to do a better job of **recycling** them. Technical, economic, and social factors have limited the success of this approach so far, and no more than 1 percent of all discarded plastics are ever recycled. Another solution is to fabricate plastics in such a way that they will degrade. Addition of starch as a filler in plastics, for example, tends to make them more **biodegradable**, that is, degradable by naturally-occurring organisms.

Yet another approach is photodegradable plastics, plastics that will decompose when exposed to sunlight. The process of photodegradation is well understood by chemists. In general, when light strikes a molecule, it may initiate any number of reactions that result in the destruction of that molecule. For example, light may dislocate one or more electrons that make up a **chemical bond** in the molecule. When the bond is broken, the molecule is destroyed.

On a practical level, that means that light can cause certain materials to decompose. Among the plastics, aromatic-based polymers (those that have benzene-like ring structures) are particularly susceptible to photodegradation. Those that lack an aromatic structure are less susceptible to the effects of light. Polyethylene, polypropylene, **polyvinyl chloride**, polymethyl methacrylate, polyamides, and polystyrene--some of the most widely used plastics--fall into that latter category.

In addition to the type of plastic, the kind of light that falls on a material affects the rate of photodegradation. Ultraviolet (UV) light is more effective, in general, in degrading all plastics than are most other forms of light.

The chemist's task, then, is to find a mechanism for converting a substance that is normally non-photodegradable (like **polystyrene**) into a form that is decomposed by light. In principle, that challenge is rather easily met. Certain metallic ions and organic groups are known to absorb visible light strongly. If these ions or groups are included in a plastic material, their **absorption** of light will contribute to the decay of the plastic.

Photodegradable plastics are not a new market item. Webster Industries, of Peabody, Massachusetts, has been making photodegradable plastic bags since 1978. And Mobil Chemical focused some of its advertising in 1990 on Hefty trash bags that were designed to photodegrade.

But critics raise a number of points about photodegradable (as well as biodegradable) plastic materials. For one thing, most plastics are disposed of in sanitary landfills where they are rapidly covered with other materials. The critics question the good of having a photodegradable plastic that is not exposed to sunlight after it is discarded.

Questions have also been raised about the possible by-products of photodegradation. It is possible that the very additives used to make a plastic photodegradable may have toxic or other harmful environmental effects, critics say.

Finally, photodegradable plastics take so long to decay (typically two months to two years) that they will still pose a hazard to **wildlife** and contribute to solid waste volume. The "false promise" of photodegradability may, in fact, actually encourage the use of more plastics and add to the present problem, rather than helping to solve it. *See also* Decomposition; Green packaging; Green products; Ultraviolet radiation

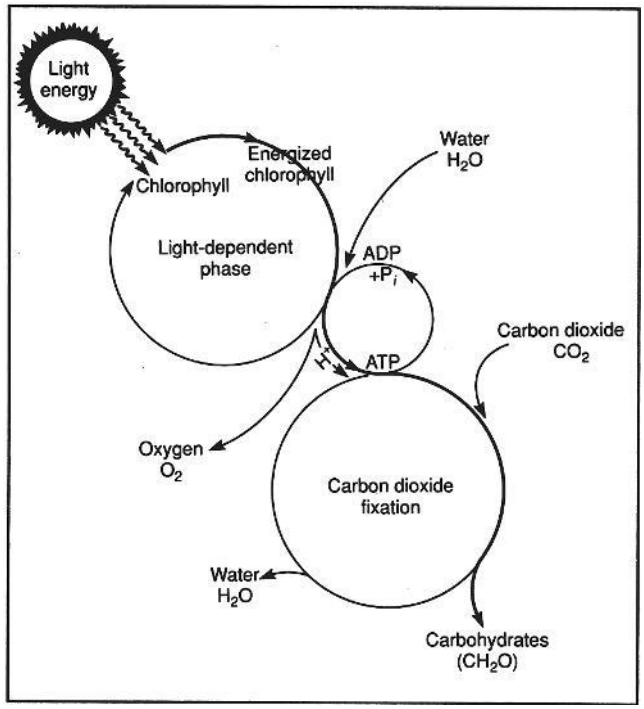
Photoperiod



The light phase in a cycle of alternating periods of light and dark. Changes in light-dark cycles, such as changes in day-length, are the most dependable external time cues (zeitgebers). The physiological response to the length of the day or night, known as photoperiodism, is mediated by an internal or biological clock that synchronizes daily activities with external light-dark cycles. Most **species** studied show a circadian or daily rhythm set to a 24-hour cycle. Organisms also show long-term photoperiodism where their seasonal activities, such as courtship, mating, reproduction, **migration**, flowering, and seed production, are coordinated with others in the population and within the community.

Photosynthesis

Photosynthesis is the process by which green plants capture sunlight and convert its kinetic energy into chemical energy by manufacturing complex sugar molecules or carbohydrates. The plants use **carbon dioxide** from the air and water as the source materials for photosynthesis. Both **carbon** dioxide and water store relatively small amounts of energy. The carbohydrates manufactured are rich in energy. Later, during the process of **respiration**, the plant breaks down these carbohydrates, and the energy that is then released is used to fuel the growth and **metabolism** of the plant. The photosynthetic process also releases oxygen along with the formation of the carbohydrates. The water (H_2O) that is used in the photosynthetic reaction contributes its **hydrogen** to the formation of the carbohydrate. The oxygen that is released comes from the remaining, unused portion of the water molecule. Therefore, water is just as essential a component as carbon dioxide to the photosynthetic process. The entire reaction is carried out with the help of green, light-sensitive pigments within the plant, known as chlorophylls.

Photosynthesis is vital to the earth in two ways. It is the process by which plant life is established, thereby providing food and supporting all the other consumers in the **food chain/web**. The release of oxygen also ensures a livable, breathable **atmosphere** for all other oxygen-dependent life forms. The maintenance of a stable balance between the processes of photosynthesis (which produces oxygen) and respiration (which consumes oxygen) is critical to the **environment**. For example, a large amount of organic matter goes into a lake receiving sewage. This organic matter will be used as a food source by bacteria which break it down by the process of respiration just as humans do. During the respiration process, the oxygen that is dissolved in the water is used up. If there is insufficient plant material in the lake to restore this used-up oxygen by photosynthesis, the total supply of **dissolved oxygen** in the waters of the lake may drop dangerously. Since fish are completely dependent on the dissolved oxygen for their breathing requirements, severe drops in the concentration of dissolved oxygen may kill the fish, leading to sudden, and sometimes massive, **fish kills**.

Another aspect of environmental **pollution** are the effects on the process of photosynthesis itself. A number of contaminants have been shown to affect plant growth and metabolism by inhibiting the plant's ability to photosynthesize. Frequently, as in the case of metals like **copper**, **lead** and **cadmium**, the mechanism of inhibition is due to the contaminant's effect on the chlorophyll pigment. Copper replaces the necessary magnesium in the chlorophyll molecule, and the copper-substituted chlorophyll cannot effectively capture light energy. Therefore, the effectiveness of the photosynthetic process is greatly diminished, which leads to a stunting of plant growth and a depletion of oxygen in the environment. The maintenance of a healthy level of photosynthesis is thus essential to the life of the planet, both on the global and the micro-environmental scales.

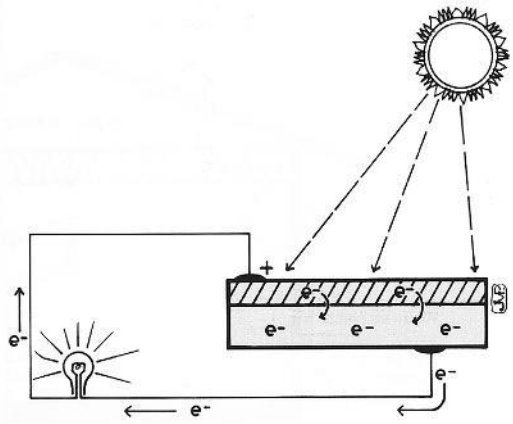
Photovoltaic cell

Photovoltaics is the direct conversion of sunlight into electrical energy using solar cells. All energy on earth is received from the sun through its electromagnetic spectrum. At any one instant, the sun delivers 1,000 watts (kw) per square meter to the earth's surface. Most of this energy is absorbed as heat by the lithosphere (**soil**), hydrosphere (water), and **atmosphere** but photovoltaic cells (PVC) are capable of converting it into a non-polluting, ecologically sound, and dependable source of electrical power. Although the photo-

voltaic effect was discovered 150 years ago, economically viable applications were not possible until the recent development of efficient semiconductor material and processing methods.



The physics of converting sunlight into electricity is simple. Most photovoltaic cells are a standard negative/positive type with attached leads. The negative terminal **lead** is soldered on the light sensitive side of the cell, and the positive lead is attached to the back side of the cell. When simply exposed to light, each cell produces about the same voltage between the two terminals. But if the cell is exposed to light when a load such as a discharged battery or an electric motor is connected between the two terminals, the voltage difference causes a flow of electrons. This current is caused by the formation of hole-electron pairs by the absorbed light photons, and the amount of current is dependent on the amount of absorbed light, which is dependent in turn on the incident light intensity and the surface area of the absorbing photovoltaic cell.

There are two main types of solar cells: thick-film cells with a thickness greater than 25 microns of crystalline silicon and thin-film cells with a thickness of less than 10 microns. Thin-film cells are made of various materials, including amorphous silicon and **copper** indium diselenide, and by combining several varieties of these in tandem, each with unique absorbing characteristics, the solar flux can be more efficiently utilized. Because these cells use less material, they are less costly to produce and will probably replace thick-film cells.

Both thick-film and thin-film cells are classified by the materials from which they are made—as crystalline (a wafer sliced from a large ingot), amorphous (The condensed gaseous form of a semi-conductor material such as silicon), and polycrystalline. Material combinations known as compound semiconductors have been investigated in the 1990s. These are cell materials whose active layers are comprised of various semiconductor materials, such as gallium arsenide, copper sulfide, and **cadmium** telluride.

To increase voltage, multiple cells are connected in a series by attaching the positive lead of one cell to the negative lead of another. The series most commonly used for both commercial and domestic applications is known as a module and usually consists of 36 cells. One or more modules can be connected directly to a load, such as a battery, a water pump, or an exhaust fan. A typical photovoltaic system consists of the modules, a storage battery, a charge and voltage regulator, and a suitable load. Some compact high performance modules are designed to charge 12-volt batteries or directly power a 12-volt DC motor.

Photovoltaic modules may be installed on a standard ground mount or on a tracker. When installed on a standard ground mount, the modules can be adjusted from 15–65 degrees at 5 degree increments. Ground mounts can support two to eight modules. The tracker utilizes a variable thermal expansion of gas, due to the changing solar exposure, and actually follows the sun at approximately 15 degrees plus latitude valve. To maximize efficiency, several modules are mounted on a tracker supported by a single pole.

The operation of a photovoltaic cell. (McGraw-Hill Inc. Reproduced by permission.)

The net cost per kilowatt hour is the most important factor in the future of photovoltaic cell production and application. In industrialized countries, the economic viability of this form of **solar energy** is determined by their cost relative to competitive energy sources, particularly **fossil fuels** and **nuclear power**, and the environmental impact of each source. The world market price for solar cells in 1993 was four dollars a watt, based on rated output, and prices are expected to drop 50% by the end of the decade, when most photovoltaic cells will be manufactured with thin-film technology.

Decentralized single dwellings, cattle ranches and tree farms remote from electric power lines, and small villages with limited power demands are one of the three market segments where photovoltaic cells can be utilized competitively. The consumer and leisure market is another, and solar cells are already widely used in boats, motor homes, and camp sites, as well as in calculators and other electronics. The third market is in industrial applications such as offshore buoys, lighthouses, illuminated road signs, and railroad and traffic signals.

The market for photovoltaic cells is increasing at an overall annual rate of about 10%. Current worldwide demand is estimated at about 100 megawatts of electrical power, and predictions for the year 2000 estimate a demand of several times this size. Growth is the fastest in the remote market; rural consumer applications are increasing at an annual rate

of approximately 35%. There are millions of people around the world who are not served by **electric utilities** due to their remote location and the high cost of electrical transmission. These populations generally depend on a 12-volt **automobile** battery powered by a generator for their electrical needs, which include water pumping, lighting, and radio and television reception. The initial cost of a photovoltaic kit offsets the cost of owning and operating a generator within three years. As the life span of a module is usually 15 years, this option is much more economical in many of these situations.

Prior to 1989, the largest manufacturer of photovoltaic cells was ARCO Solar, a division of Atlantic Richfield Oil Company. In 1989, Siemens Solar Industries (SSI), which already had a joint manufacturing enterprise in Munich, Germany, with ARCO, had purchased ARCO Solar. SSI has manufacturing plants in Camarillo, California, and Munich, Germany.

Converting sunlight into electricity with photovoltaic cells is a versatile and simple process. Unlike diesel or **gasoline** generators, all-weather modules have no moving parts to wear out or break down, and they produce electricity without contributing to **air pollution**. Solar cells do not produce any noise and they do not require alternating-current power lines, since photovoltaic electricity is direct current. Maintenance is minimal and requires little technical skill; systems are easy to expand and there are no expensive fuels to purchase on a continuous basis. Photovoltaic cells are a cheap and dependable source of power for a variety of uses. *See also* Alternative energy sources; Alternative fuels; Energy and the environment; Energy policy

Phthalates

Phthalates are aromatic compounds that are found throughout the **environment** and are used in some **plastics**, solvents, **detergents**, lubricating oils, and cosmetics. There is concern that phthalates can cause **cancer** or reproductive problems in people and animals. In 1998, the U.S. Consumer Product Safety Commission (CPSC) conducted a study of the amount of one type of phthalate, diisononyl phthalate (DINP) that can leach from children's products such as teethers, rattles, and toys. This study set an international standard concentration for DINP in children's products that is 10 times higher than the level found to cause health problems in laboratory animals. The results of a study released in 2000 by the **Centers for Disease Control and Prevention** (CDC) and the National Toxicology Program (NTP) found four types of phthalates in the urine of more than 75% of test subjects, indicating that the phthalates that humans are exposed to in the environment are metabolized. The study was not designed to provide information on the health risks of phthalates or on the degree of exposure of the United States population, and follow-up studies by the CDC are measuring phthalate concentrations in a larger part of the population, including children six years old and older.

Phytoplankton

Photosynthetic **plankton**, including microalgae, blue-green bacteria, and some true bacteria. These organisms are produced in surface waters of aquatic ecosystems, to depths where light is able to penetrate. Sunlight is necessary since, like terrestrial plants, phytoplankton use solar radiation to convert **carbon dioxide** and water into organic molecules such as glucose. Phytoplankton form the base of nearly all aquatic food chain/webs, directly or indirectly supplying the energy needed by most aquatic protozoans and animals. Temperature, **nutrient** levels, light intensity, and consumers (grazers) are among the factors that influence phytoplankton community structure.

Phytoremediation

Phytoremediation combines the Greek word *phyton*, "plant," with the Latin word *remediare,* "to remedy," to describe a system whereby certain plants, working together with **soil** organisms, can transform contaminants into harmless and often, valuable, forms. This practice is increasingly used to remediate sites contaminated with **heavy metals** and toxic organic compounds.

Phytoremediation takes advantage of plants' **nutrient** utilization processes to take in water and nutrients through roots, transpire water through leaves, and act as a transformation system to metabolize organic compounds, such as oil and pesticides. Or they may absorb and bioaccumulate toxic trace elements, such as the heavy metals, **lead**, **cadmium**, and selenium. In some cases, plants contain 1,000 times more metal than the soil in which they grow. Heavy metals

are closely related to the elements plants use for growth. In many cases, the plants cannot tell the difference, according to Ilya Raskin, Professor of Plant Sciences in the Center for Agricultural Molecular Biology at Rutgers University.

Phytoremediation is an affordable technology that is most useful when contaminants are within the root zone of the plants (top 3-6 ft [1-2 m]). For sites with contamination spread over a large area, phytoremediation may be the only economically feasible technology. The process is relatively inexpensive because it uses the same equipment and supplies used in agriculture.

Soil **microorganisms** can degrade organic contaminants. This is called **bioremediation** and has been used for many years both as an in situ process and in land farming operations with soil removed from sites.

Ilya Raskin and his interdisciplinary team at Rutgers AgBiotech Center were first to demonstrate the utility of certain varieties of mustard plants in removing such metals as chromium, lead, cadmium, and zinc from **contaminated soil**. Related technology developed by Raskin's group used hydroponic plant cultures to remove toxic metals from aqueous waste streams.

Plants can accelerate bioremediation in surface soils by their ability to stimulate soil microorganisms through the release of nutrients from and the transport of oxygen to their roots. The zone of soil closely associated with the plant root, the rhizosphere, has much higher numbers of metabolically active microorganisms than unplanted soil. The rhizosphere is a zone of increased microbial activity and **biomass** at the root-soil interface that is under the interface of the plant roots. It is this symbiotic relationship between soil **microbes** that is responsible for the accelerated degradation of soil contaminants.

The interaction between plants and microbial communities in the rhizosphere is complex and has evolved to the mutual benefit of both organisms. Plants sustain large microbial populations in the rhizosphere by secreting substances such as carbohydrates and amino acids through root cells and by sloughing root epidermal cells. Also, root cells secrete mucigel, a gelatinous substance that is a lubricant for root penetration through the soil during growth. Using this supply of nutrients, soil microorganisms proliferate to form the plant rhizosphere.

In addition to this rhizosphere effect, plants themselves are able to passively take up a wide range of organic wastes from soil through their roots. One of the more important roles of soil microorganisms is the **decomposition** of organic residues with the release of plant nutrient elements such as **carbon**, **nitrogen**, potassium, phosphate, and sulfur. A significant amount of the **carbon dioxide** (CO_2) in the **atmosphere** is utilized for organic matter synthesis primarily through **photosynthesis**. This transformation of carbon dioxide and the subsequent sequestering of the carbon as root biomass contributes to balancing the effect of burning **fossil fuels** on global warming or cooling.

Compounds are frequently transformed in the plant tissue into less toxic forms or sequestered and concentrated so they can be removed (harvested) with the plant. For example, mustard greens were used to remove 45% of the excess lead from a yard in Boston, Massachusetts, to ensure the safety of children who play there. The sequestered lead was carefully removed and safely disposed of. Besides mustard greens, pumpkin vines were used to clean up an old Magic Marker factory site in Trenton, New Jersey. Hydroponically grown sunflowers were used to absorb radioactive metals near the Chernobyl nuclear site in the Ukraine and a **uranium** plant in Ohio. The mustard's hyper-accumulation results in much less material for disposal. The **composting** of plant material can be another highly efficient stage in the breakdown of contaminants removed from the soil.

When trees are used, such as poplars, the idea is to move as much water through them as possible, so that they take up as much of the contaminants as possible. Once the heavy metals are absorbed, they are sequestered in the trees' roots. Any organic compounds that are absorbed are metabolized.

Absorption of large amounts of nutrients by plants and only a small amount of plant **toxins** that might be harmful to them, is the key factor. Plants generally absorb large amounts of elements they need for growth and only small amounts of toxic elements that could harm them. Therefore, phytoremediation is a cost-effective alternative to conventional **remediation** methods. Cleaning the top 6 in (15 cm) of contaminated soil with phytoremediation costs an estimated $2,500-$15,000 per hectare (2.5 acres), compared to $7,500-$20,000 per hectare for on-site microbial remediation. If the soil is moved, the costs escalate, but phytoremediation costs are still far below those of traditional remediation methods, such as stripping the contaminants from the soil using physical, chemical, or thermal processes, according to Dr. Scott Cunningham, a scientist at Dupont Central Research for Environmental Biotechnology.

Plants are effective at remediating soils contaminated with organic chemical wastes, such as solvents, petrochemicals, wood preservatives, explosives, and pesticides. The conventional technology for soil clean-up is to remove the soil and isolate it in a **hazardous waste landfill** or incinerate it.

Phytoremediation, says Dr. Ray Hinchman, botanist and plant physiologist at Argonne National Laboratory, is "an *in situ* approach," not reliant on the transport of contaminated material to other sites. Organic contaminants are, in many cases, completely destroyed (converted to CO_2 and H_2O) rather than simply immobilized or stored.

Salt-tolerant plants, called halophytes, have reduced the salt levels in soils by 65% in only two years in one project involving brine-damaged land from run-off from oil and gas production in Oklahoma. After the salt was reduced, the halophytes died and native grasses, which failed to thrive when too much salt entered the soil, naturally returned, replacing the salt-converting plants.

The establishment of vegetation on a site also reduces soil **erosion** by wind and water, which helps to prevent the spread of contaminants and reduces exposure of humans and animals.

Classes of organic compounds that are more rapidly degraded in rhizosphere soil than in unplanted soil include: total **petroleum hydrocarbons**; **polycyclic aromatic hydrocarbons**; chlorinated pesticides (PCP, **2,4-D**); other chlorinated compounds (PCBs, TCE); explosives (TNT, DNT); **organophosphate** insecticides (diazanon and parathion); and surfactants (**detergents**).

Some plants used for phytoremediation are: alfalfa, symbiotic with hydrocarbon-degrading bacteria; arabidopsis, carries a bacterial gene that transforms **mercury** into a gaseous state; bladder campion, accumulates zinc and **copper**; brassica juncea (Indian mustard greens), accumulates selenium, sulfur, lead, chromium, cadmium, **nickel**, zinc, and copper; buxaceae (boxwood), accumulates nickel; compositae family (symbiotic with arthrobacter bacteria), accumulates cesium and strontium; euphorbiaceae (succulent), accumulates nickel; ordinary tomato, accumulates lead, zinc, and copper; poplar, used in the absorption of the **pesticide**, **atrazine**; and thlaspi caerulescens (alpine pennycress), accumulates zinc and cadmium.

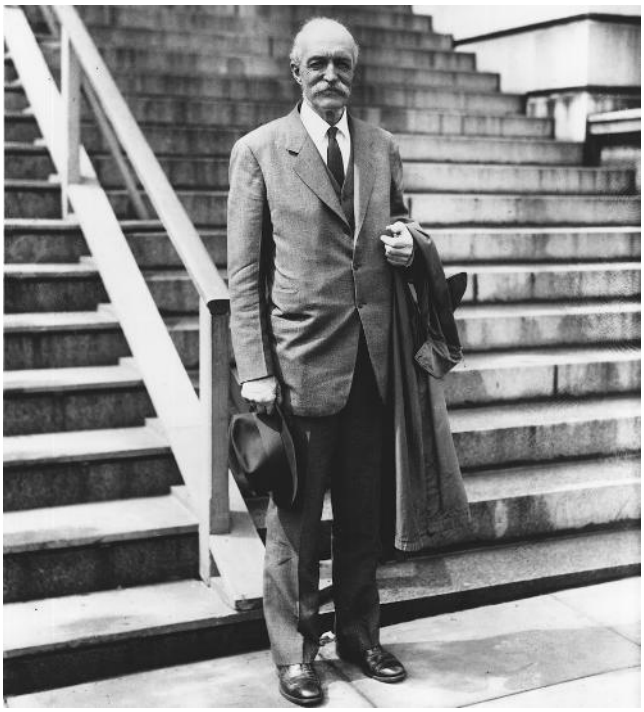
Phytotoxicity

Phytotoxicity refers to the damage to plants caused by exposure to some toxic stressor. Phytotoxicity can be evidenced by acute injury such as obviously damaged, necrotic tissues. Chronic phytotoxicity does not present such obvious symptoms and may result in such "hidden injuries" as a decrease in productivity or a change in growth form. Plants can be poisoned by naturally occurring **toxins**, such as **nickel** in serpentine-influenced soils. Humans also release phytotoxic **chemicals** into the **environment**. Such emissions occur when, for example, gaseous and/or metal pollutants around smelters damage vegetation. Deliberate use of phytotoxic chemicals includes the use of herbicides in agriculture or forestry to decrease the abundance of unwanted plants or weeds.

Gifford Pinchot (1865 – 1946)

American conservationist and forester



Pinchot was born in Simsbury, Connecticut, to a prosperous business and industrial family, part of whose wealth came from timber holdings in several states. The Pinchots, like other lumber investors of their day, practiced **clear-cutting** on forests to maximize their profits, shipped the logs to market, and with the returns, repeated the cycle. Young Gifford was pressured by his grandfather to enter the family business, but his father James was beginning to dislike the **deforestation** of his area, and he encouraged his son to pursue forestry.

Pinchot was educated at Exeter and then Yale, graduating in 1889. After graduation, his family supported further education at L'Ecole nationale forestiere in Nancy, France, where he studied silviculture, or forest **ecology**. It was in Nancy that he learned "*le coup d'oeil forestier*—the forester's eye, which sees what it looks at in the woods." In his 1947 book, *Breaking New Ground*, Pinchot noted that it was in France that he began to think of "the forest as a crop," that forests could sustain human use by a "fixed and annual supply of trees ready for the axe."

Returning to the United States in 1892, Pinchot engaged in "the first scientific forestry in America" on the Vanderbilt estate in North Carolina, hoping to prove that "trees could be cut and the forest preserved at one and the same time." Pinchot figured out how to sustain the forest while maintaining its yield, and thus its income. He called his first successful year "a balance on the side of practical forestry."

Pinchot then worked as a consulting forester in New York City, where he attracted increasing attention for his ideas. The National Academy of Science appointed him to the new National Forest Commission, organized by the **U.S. Department of the Interior**. On the Commission's recommendation, President Grover Cleveland added 13 more forest reserves totaling 21 million acres (8.5 million ha). Pinchot, voicing a minority opinion on the Commission,

Gifford Pinchot. (Corbis-Bettmann. Reproduced by permission.)

saw the reserves as property for public use, not as a way to lock up the nation's **natural resources**.

In 1898 Pinchot became head of the U.S. Department of Agriculture's Division of Forestry. The division did not operate the nation's forest reserves, which were then administered by the Department of the Interior's General Land Office. Pinchot lobbied hard to have the reserves transferred to his division, but his efforts were unsuccessful until William McKinley's assassination moved **Theodore Roosevelt** into the White House. Pinchot and Roosevelt together mustered enough support in Congress to approve the transfer to the renamed Bureau of Forestry in 1905, marking the beginning of the national forest system and what became the U.S. **Forest Service**.

Pinchot's long-time collaboration with Roosevelt was one of the benchmarks of the **conservation** movement, which culminated in the creation of what have been called the "midnight forests." These 16 million acres of forest were set aside as reserves late in the night before a Congressional bill to limit the President's power to do so took effect. After Roosevelt left office, Pinchot's association with President William Howard Taft soured quickly, climaxing in a feud with Richard Ballinger, Taft's Secretary of the Interior and ending in 1910, when Pinchot was fired by the President.

Despite leaving before he had accomplished all that he wished, Pinchot left his mark on the Forest Service. Ironically, both are often criticized by modern environmentalists for their utilitarian policies. Yet this early conservationist was one of first to protect national forest lands from the industrial powers who sought to destroy them completely.

Pinchot still generates controversy today. Most writers trace the conflict between conservationists and preservationists to his falling-out with **John Muir** over the Hetch-Hetchy Reservoir in California. Pinchot, with his pragmatic approach, argued that the river valley served the greatest public good as a dependable source of water for the people of San Francisco. Muir maintained that Hetch Hetchy was sacred and too beautiful to flood. He also believed the dam would betray the **national park** ideal, since Hetch Hetchy was in **Yosemite National Park**.

As he grew older, Pinchot did become less utilitarian, creating what he called the "new conservationism," but even his "new" approach was an extension of his long-held conviction that the forests of the nation belonged first to the people, to be used by them wisely and in perpetuity. To Pinchot, conservation meant "the greatest good to the greatest number for the longest time." Pinchot's beliefs, which have been revived in recent years, make sense both ecologically and economically. He claimed that "the central thing for which Conservation stands is to make this country the best possible place to live in, both for us and our descendants."

Pinchot was active on many fronts of the struggle for conservation. The **Society of American Foresters**, a professional association and major force in resource management and conservation today was created in 1900, due in part to his efforts. He served two terms as Governor of Pennsylvania (1923–27; 1931–35), and his efforts to relieve the effects of the Great Depression led to the creation of emergency work camps there, providing a model for the Civilian Conservation Corps started by President Franklin Roosevelt.

Pinchot recognized that people *must* live off the resources of land where they live. In *The Fight for Conservation* (1910), he stated bluntly that "the first principle of conservation is development, the use of the natural resources now existing on the continent for the benefit of the people who live here now." But, he also recognized that use of resources could quickly turn into abuse of resources, especially by exploitation for the few. He believed that destruction of forest resources was detrimental to the **environment** and to the many who depended on it.

Pinchot's ideas and his national forests are still with us today. His concern with producing the greatest totality of **land use** produced the **wilderness** that is preserved but

accessible and forest that is logged and renewed. Pinchot, a giant of the conservation and the environmental movements, leaves his legacy of a vast forest domain that belong to the American people.

Placer mining

Placer deposits are collections of some mineral existing in discrete particles, mixed with sand, gravel, and other forms of eroded rock. Some of the minerals most commonly found in placer deposits are diamond, gold, platinum, magnetite, rutile, monazite, and cassiterite. These deposits are formed by the action of wind, water, and chemical changes on more massive beds of the mineral. Placer deposits can be classified according to the method by which they are produced. Some examples include stream placers, eolian placers (formed by the action of winds), beach placers, and moraine placers (formed by glacial action).

Placer deposits are important sources of some minerals that are more dense than the sand or gravel around them. For example, the gold in a placer deposit tends to settle out and accumulate in a stream as surrounding materials wash away.

With few exceptions, the mining of placer deposits is carried out by traditional surface (compared to underground) mining. Four general methods are in use. The oldest and perhaps most familiar to the general public is the hand method. Placerville, California, commemorates by its name the type of mining that was done during the Gold Rush of 1849. As the worker rocks his or her box or pans back and forth, clay and sand are washed away, and the heavier gold (or other minerals) settles to the bottom. This method is less used today since deposits with which it works best have been largely depleted.

Artificial streams of water are used in a second method of placer mining--hydraulic mining. In this process, intense streams of water are directed with large hoses at a placer deposit. The water washes away the overlying sand and clay, leaving behind the desired mineral.

A number of variations of this procedure exists. In some cases, a natural stream is diverted from its course and directed against a placer deposit. The action of the stream substitutes for that of a hose in the traditional hydraulic method. In another variation, a stream may be dammed rather than diverted. When the dam is broken, the penned-up water is released all at once with a force that can tear apart a placer deposit. This technique is known as "booming" a deposit and although it is no longer used in the United States, the method is used around the world.

An increasingly popular approach to placer mining makes use of familiar **surface mining** machinery used to extract **coal** and other minerals. This machinery is often very large and efficient. It removes **overburden**, extracts mineral-containing earths with streams of water and then separates and processes the extracted material by gravity methods.

A fourth method of mining is used with deposits underwater, as in a lake or along the seashore. In this process, a large machine somewhat similar to a surface mining excavator is placed on a barge. The machine then scoops materials off the lake, stream, or ocean bottom and carries them to a processing area on another part of the barge. This type of **dredging** machine might be thought of as a very large, mechanized version of the old prospector's gold pan and rocker box.

Placer mining poses two kinds of environmental problems. The first is one that is common to all types of surface mining, the disturbance of land. Federal law now requires that land disturbed by surface mining such as placer mining be restored to a condition that approximates its original state.

The extensive use of water during placer mining is a second source of concern. By its nature, placer mining produces huge flows of water that have become contaminated with mud, sand, and other suspended solids. As this water is dumped into natural waterways, these solids may damage aquatic plant and animal life and, as they settle out, create new navigational hazards. In the United States, the Clean Water Acts and other environmental laws carry provisions to reduce the potential harm posed by placer mining.

Plague

For centuries past, plague was the scourge of the earth, killing at least an estimated 163 million people during three major worldwide pandemics. Today, plague still exists in the world although the number of cases and deaths is much lower. Plague still infects several thousand people a year and kills several hundred. Most cases are in southern Africa, Asia, and central South America.

Plague is an infectious disease that affects animals and humans. It is caused by the bacterium *Yersinia pestis* and is usually found in rodents and their fleas. When released into the air, the bacterium can survive for up to an hour. People usually contract the disease after being bitten by an infected flea or after handling an infected animal. To reduce the risk of death, antibiotics must be given within 24 hours after the first symptoms occur.

There are three types of plague and they can occur separately or in combination. The types are:

- Bubonic plague, the most common form of the disease. It does not spread from person to person but is transmitted when an infected flea bites a person or when material contaminated with the bacterium enters through a cut in a person's skin. Symptoms include swollen lymph glands, fever, headache, chills, and weakness.
- Pneumonic plague, which infects a person through the lungs. It can be spread in the air from person to person. Symptoms include fever, headache, weakness, shortness of breath, chest pain, cough, and pneumonia.
- Septicemic plague, which occur when plague bacteria multiply in the blood. It can occur by itself or be a complication of pneumonic or bubonic plague. It is not spread from person to person. Symptoms include fever, chills, exhaustion, abdominal pain, shock, and bleeding into the skin and other organs.

To reduce the chance of death, people with plague must receive antibiotics within 24 hours after the first symptoms appear. Effective antibiotics include streptomycin, gentamicin, and tetracycline. Early treatment allows most people with plague to be cured if diagnosed in time. There is no vaccine against plague available.

From 1954 to 1997, there were 80,613 reported plague cases in 38 countries, of which 6,587 people died, according to the World Health Organization (WHO). The highest number of cases, 6,004, occurred in 1967, and the lowest number, 200, occurred in 1981. These numbers likely represent only about a third of the actual number of cases, due to inadequate surveillance and reporting methods, according to WHO.

Plague has been around since the dawn of civilization and probably existed in animals before humans inhabited the earth. The first recorded plague epidemic occurred in 1320 BC and is described by its symptoms in the Bible (I Samuel, V and VI). It is not known how many people were infected. The first known pandemic, or severe worldwide epidemic, occurred in Asia, Africa, and Europe between 542 and 546 AD. It was named Justinian's plague, after the emperor of the Byzantine Empire at the time, and killed an estimated 50 million to 100 million people.

The first pandemic is believed to have started in Egypt, spreading north through the eastern Mediterranean. The plague struck at a critical time. In Constantinople, the capital of the Byzantine empire, Justinian and his generals were in the midst of battles to rejoin Byzantium to the remains of Western Roman Empire. Justinian's dream was to re-establish the former Roman Empire; and he might have succeeded if not for the plague. Procopius, a historian living in Constantinople at the time, vividly described the plague and its effects. His writings also include an accurate description of what would later be called the bubonic plague. He wrote about agitated, feverish disease victims with painfully enlarged lymph nodes (buboes) under their arms and in their groins. According to Procopius, 300,000 people died within the city alone. It is impossible to verify whether that figure is accurate, but it is certain that the plague had a dramatic effect on history. Justinian's plans to re-establish the Roman Empire were very likely derailed because of the loss of manpower. In the west, the remnants of the Western Roman Empire collapsed into the Dark Ages.

Following the initial outbreak in 542, the plague disappeared and reappeared at intervals over the next 200 years. The years 542 to 600 were the most intense plagues years, but local epidemics flared up throughout the Mediterranean region through the mid-eighth century. The population of Europe wasn't able to recover between outbreaks and some historians estimate that the population dropped by half between 542 and 700. After the late-eighth century, plague disappeared from Europe for nearly 600 years.

The second pandemic is the infamous "Black Death" from 1347 to 1350 AD. It killed from 25 million to 50 million

people, half in Asia and Africa and half in Europe (a quarter of the population). Its entry into Europe was through Kaffa, a small Italian trading colony on the shore of the Black Sea in Crimea. Kaffa was besieged by an army and during the siege, plague broke out among the soldiers. According to some sources, the soldiers threw the corpses of those who died over the town walls to spread plague among the men defending the town. Whether that caused plague to break out in the town is unknown, but the defenders were afflicted. They managed to get to their boats and flee to Italy, unknowingly carrying the disease with them.

By late 1347, plague was widespread in the Mediterranean region, and in 1348 it spread throughout Italy, France, and England. The Middle East and the Far East were also severely affected. Medieval physicians were at a loss to explain the disease. Some claimed it was due to person-to-person infection, while others said it arose from a poisonous **atmosphere**. Other explanations put forth by panicked citizens blamed astrological influences, divine punishment, and the Jewish community. Tens of thousands of Jewish citizens were burned in Spain, Germany, Switzerland, and France despite protests by Pope Clement VI, Emperor Charles IV, and medical experts who said that they were innocent. However, the authorities were powerless to stop the spread of plague, and they were not believed. Quarantines of plague victims were ordered, but they were largely ineffective.

The Black Death was the beginning of a number of plague outbreaks that ravaged Europe and Africa in subsequent centuries. In England alone, there were plague outbreaks in 1361, 1369, 1390, 1413, 1434, 1439, and 1464. Additional outbreaks occurred in Scotland in 1401–1403, 1430–1432, and 1455. The epidemics cut England's population of about seven million in half from 1300 to 1380. The last major outbreaks of the Black Death pandemic occurred in London in 1665–1666 and in Marseilles in 1720–1722. Each of these outbreaks resulted in approximately 100,000 deaths.

In a controversial 2001 book, "Biology of Plagues," authors and epidemiologists Susan Scott and Christopher Duncan write they believe the plague of 1347–1351 was not caused by the bubonic plague, but rather by a still unknown disease. They say the quick spread of the disease and the fact that bubonic plague is not transmitted person to person, as the Black Death was, points to another cause. Another possibility, however, is that the ship trade of that time would have allowed for disease-infested rats to move from location to location rapidly and thus, spread the disease quickly through various populations.

The world's third plague pandemic began in 1894 in China and Hong Kong. Called the Modern Pandemic, it quickly spread throughout the world, carried by rats aboard steamships. From 1894 through 1903, plague-infested ships had brought the disease to 77 ports in Asia, Africa, Europe, North America, **Australia**, and South America. In India alone, plague killed about 13 million people. In the year the pandemic started, scientists discovered the cause of the disease, and established that rats and their fleas were the carriers.

According to most sources, the Modern Pandemic continues to the present time. Epidemics linked to the Modern pandemic were reported in San Francisco, New Orleans, and other coastal cities throughout the world and millions died. The Modern pandemic also established in areas that previously had been plague free, including North America, South America, and southern Africa. With the advent of antibiotics and the understanding of how plague spreads, the Modern pandemic has been contained and the plague no longer claims millions of victims. However, health authorities remain vigilant because the plague has not been eradicated.

At the turn of the twentieth century, plague outbreaks twice hit San Francisco. The first outbreak was from 1900 to 1904, and the second from 1907 to 1909. Several hundred infections were confirmed but health officials believe hundreds of cases went unreported. More recently, an outbreak of bubonic plague occurred in the African nation of Malawi in early 2002, infecting at least 10 people

The decrease in the incidence of plague today is due primarily to improved living standards and health services in many underdeveloped nations. In India, plague epidemics have stopped altogether. The reasons for this are not clear, according to WHO scientists. The Government of India, however, has taken a number of stringent measures to prevent spread of the disease. These include mandatory screening at airports of every airline passenger intending to travel abroad for signs and symptoms of plague, **fumigation** of aircraft, including both the passenger cabin and the cargo hold. Additionally, all aircraft are inspected for the presence of rats. At all major sea ports, all out-going vessels are being inspected for the presence of rats and insects. Ships are required to have a certificate, issued by the port health officer, showing that they have been deratted, before they can leave port. All these measures are in accordance with the WHO International Health Regulations.

Plague is often mentioned as a potential biological weapon of terrorists. When released into the air, the bacterium can survive for up to an hour. Of the three types of plague (pneumonic, bubonic, and septicemic), pneumonic is they one most likely to be used by terrorists since large stockpiles were developed by the United States and Soviet Union in the 1950s and 1960s. Much of the Soviet supply is now in the hands of several of its former republics, now independent nations. The U.S. government believes several so-called "rogue" nations, such as Iran, Iraq, and North

Korea, have biological weapons programs. While several other nations presumably have biological weapons programs, these nations pose a more significant threat to the United States and its allies.

Plankton

Organisms that live in the water column, drifting with the currents. Bacteria, **fungi**, algae, protozoans, invertebrates, and some vertebrates are represented, some organisms spending only parts of their lives (e.g. larval stages) as members of the plankton. Plankton is a relative term since many planktonic organisms possess some means by which they may control their horizontal and/or vertical positions. For example, organisms may possess paddle-like flagella for propulsion over short distances, or they may regulate their vertical distributions in the water column by producing oil droplets or gas bubbles. Plankton comprise a major item in aquatic food chain/webs. *See also* Phytoplankton; Zooplankton

Plant pathology

Plant pathology is the study of plant diseases. The most common causes of plant diseases are bacteria, **fungi**, algae, viruses, and roundworms. Plant diseases can drastically affect a country's economy. They may be responsible for the loss of up to ten percent of human crops each year. Plant pathology is also important in environmental studies. Many plants are especially sensitive to pollutants in the air and water. They can be used as "early warning systems" of **pollution** problems that may affect humans as well. For example, **ozone** at a concentration of only 0.005 **parts per million** produces noticeable changes in **tobacco** plants.

Plasma

The term plasma has two major definitions in science. In biology, it refers to the clear, straw-colored liquid portion of blood. In physics, it refers to a state of matter in which atoms are completely ionized. By this definition, a plasma consists entirely of separate positive and negative ions. Plasmas of this kind exist only at high temperatures. The study of plasma is extremely important in research on **nuclear fusion**. One of the most difficult problems in that research is to find ways of physically containing a plasma in which fusion reactions are occurring.

Plastics

The term plastic refers to any material that can be shaped or molded. In this sense, ordinary clay or a soft wax is a plastic material. Perhaps more commonly, plastic has become the term used to describe a class of synthetic materials more accurately known in chemistry as polymers. Some common examples of plastics are the polyethylenes, polystyrenes, vinyl polymers, methyl methacrylates, and polyesters. These synthetic materials may or may not be "plastic" in the pliable sense.

Research on plastic-like materials began in the mid-nineteenth century. At first, this research made use of natural materials. Credit for discovery of the first synthetic plastic is often given to the American inventor, John Wesley Hyatt. In 1869, Hyatt was awarded a patent for the manufacture of a hard, tough material made out a natural cellulose. He called the product "celluloid."

It was not until 1907, however, that an entirely synthetic plastic was invented. In that year, the Belgian-American chemist Leo Baekeland discovered a new compound that was hard, water- and solvent-resistant and electrically non-conductive. He named the product Bakelite. Almost immediately, the new material was put to use in the manufacture of buttons, radio cases, telephone equipment, knife handles, counter tops, cameras, and dozens of other products.

Today, thousands of different plastics are known. Their importance is illustrated by the fact that of the 50 **chemicals** produced in the greatest volume in the United States, 24 are used in the production of polymers. Products

that were unknown until the 1920s are now manufactured by the millions of tons each year in the United States.

Despite the bewildering variety of plastics now available, most can be classified in one of a small number of ways. First, all plastics can be categorized as thermoplastic or thermosetting. A thermoplastic polymer is one that, after being formed, can be re-heated and re-shaped. If you warm the handle of a toothbrush in a flame, for example, you can bend it into another shape. A thermosetting polymer is different, however, since, once formed, it can be re-heated, but not re-shaped.

Polymers can also be classified according to the chemical reaction by which they are formed. Addition polymers are formed when one kind of molecule reacts with a second molecule of the same kind. This type of reaction can occur only when the molecules involved contain a special grouping of atoms containing double or triple bonds.

As an example one molecule of ethylene can react with a second molecule of ethylene. This reaction can continue, with a third ethylene molecule adding to the product. In fact, this reaction can be repeated many times until a very large molecule, polyethylene, results.

The prefix *poly-* means "many" indicating that many molecules of ethylene were used in its production. In the formation of a polymer like polyethylene, "many" can be equal to a few hundred or few thousand ethylene molecules. The basic unit of which the polymer is made (ethylene, in this case) is called the monomer. The process by which monomers combine with each other many times is known as polymerization.

A second type of polymer, the condensation polymer, is formed when two different molecules combine with each other through the loss of some small molecule, most commonly, water. For example, Baekeland's original Bakelite is made by the reaction between a molecule of phenol and a molecule of formaldehyde. Phenol and formaldehyde fragments condense to make a new molecule (C_6H_5CHO) when water is removed. As with the formation of polyethylene, this reaction can repeat hundreds or thousands of times to make a very large molecule.

The names of polymers often reveal how they are made. For example, polyethylene is made by the polymerization of ethylene, polypropylene by the polymerization of propylene, and **polyvinyl chloride** by the polymerization of **vinyl chloride**. The names of other polymers give no hint as to the way they are formed. One would not guess, for example, that nylon is a condensation polymer of adipic **acid** and hexamethylene diamine or that Teflon is an addition polymer of tetrafluorethylene.

Listing all the uses to which plastics have been put is probably impossible. Such a list would include squeeze bottles, electrical insulation, film, indoor-outdoor carpeting, floor tile, garden hoses, pipes for plumbing, trash bags, fabrics, latex paints, adhesives, contact lenses, boat hulls, gaskets, non-stick pan coatings, insulation, dinnerware, and table tops.

Plastics technology has become highly sophisticated in the last few decades. Rarely is a simple polymer used by itself in a product. Instead, all types of additives are available for giving the polymer special properties. Ultraviolet stabilizers, as one example, are added to absorb ultraviolet light that would otherwise attack the polymer itself. Many polymers become stiff and brittle when exposed to ultraviolet light.

Plasticizers are compounds that make a polymer more flexible. Foaming agents are used to convert a polymer to the kind of foam used in insulation or cooler chests. Fillers are materials like clay, alumina, or **carbon** black that add properties such as color, flame **resistance**, hardness, or chemical resistance to a plastic.

Some of the most widely used additives are reinforcing agents. These are fibers made of carbon, boron, glass, or some other material that add strength to a plastic. Reinforced plastics find application in car bodies and boat hulls and in many kinds of sporting equipment such as football helmets, tennis rackets, and bicycle frames.

One of the most interesting new variations in polymer properties is the development of conducting polymers. Until 1970, the word plastic was nearly synonymous with electrical non-conductance. In fact, one important use of plastics has been as electrical insulation. In 1970, however, a Korean university student accidentally produced a form of polyacetylene that conducts electricity.

For a number of reasons, that discovery did not lead to a commercial product until 1975. Then, two researchers at the University of Pennsylvania discovered that adding a small amount of iodine to polyacetylene increases its conductivity a trillion times.

A number of technical problems remain, but the day of plastic batteries is no longer a part of the distant future. Indeed, scientists are now studying dozens of ways in which conduction plastics can be substituted for metals in a variety of applications.

For all their many advantages, plastics have long posed some difficult problems for the **environment**. Perhaps the most serious of those problems, is their **stability**. Since plastics have not occurred in **nature** for very long, **microorganisms** that can degrade them have not yet had an opportunity to evolve. Thus, plastic objects that are discarded may tend to remain in the environment for hundreds or thousands of years.

Sometimes, this problem translates into one of sheer volume. In 1988, for example 19.9 percent by volume of all municipal solid wastes consisted of plastic products. That

translated into 14.4 million tons of waste products, third only to paper products and yard and food wastes. At other times, the stability of plastics is actually life-threatening to various organisms. Stories of aquatic birds who are strangled by plastic beer can holders are no longer news because they occur so often.

The presence of plastics can interfere with some of the methods suggested for dealing with solid wastes. For example, **incineration** has been recommended as a way of getting rid of wastes and producing energy at the same time. But the **combustion** of some types of plastics results in the release of toxic hydrochloric acid, **hydrogen** cyanide, and other hazardous gases.

Scientists are now moving forward in the search for ways of dealing with waste plastic materials. Some success has been achieved, for example in the development of photodegradable plastics, polymers that degrade when exposed to light. One problem with such materials is that they are often buried in landfills and are never exposed to sunlight.

Research also continues to progress on the **recycling** of plastics. A major problem here is that some kinds of polymers are more easily recycled than others, and separating one type from the other is often difficult to accomplish in everyday practice.

The use of plastics is also interconnected with the world's energy problems. In the first place, the manufacture of most plastics is energy intensive. It takes only 24 million **Btu** to make one ton of steel, but 49 million Btu to make one ton of polyvinyl chloride and 106 million Btu to make one ton of low-density polyethylene.

Perhaps even more important is the fact that **petroleum** provides the raw materials from which the great majority of plastics are made. Thus, as our supplies of petroleum dwindle, as they inevitable will, scientists will have to find new ways to produce plastics. While they will probably be able to meet that challenge, the change-over from an industry based on petroleum to one based on other raw materials is likely to be long, expensive, and disruptive.

Plate tectonics

Anyone who looks carefully at a map of the Atlantic Ocean is likely to be struck by an interesting point. The eastern coastline of South America bears a striking similarity to the western coastline of Africa. Indeed, it looks almost as if the two continents could somehow fit together--provided, of course, one could find a way to slide the land masses across the ocean floor.

The match of coastlines was noticed by scholars almost as soon as good maps were first available in the late fifteenth century. In 1620, for example, the English philosopher **Sir Francis Bacon** commented on this fact and argued that the match was "no mere accidental occurrence."

One obvious explanation for the South America-Africa fit was that the two continents had once been connected and had somehow become separated in the past. A few early scientists tried to use the Biblical story of The Flood to show how that might have happened. But as Biblical explanations for natural phenomena began to lose credibility, this approach was discarded.

That made the concept of moving continents even more difficult to believe. The earth's crust was generally thought to be solid and immoveable. How could one or two whole continents somehow slide through such a material?

Yet, over time, more and more evidence began to accumulate, supporting the notion that South America and Africa might once have been joined to each other. Much of that early evidence came from the research of the German geographer, Alexander von Humboldt. Von Humboldt spent a number of years traveling through South America, Africa, and other parts of the world. In his journeys, he collected plant and animal specimens and studied geological and geographic patterns. He was struck by the many similarities he observed between South America and Africa, similarities that went far beyond an obvious geographic fit of continental coastlines.

For example, he observed that mountain ranges in Brazil that end at the sea appear to match other mountain ranges in Africa that began at the coastline. He noted similar patterns among mountain ranges in Europe and North America.

During the nineteenth century, similarities among **fauna** and **flora** on either side of the Atlantic were observed. Although **species** in eastern South America do differ to some extent from those in western Africa, their similarities are often striking. Before long, similarities across other oceanic gaps began to be noted. Plant and animal fossils found in India, for example, were often remarkably similar to those found in **Australia**.

Attempts to explain the many similarities in various continental properties were consistently stymied by the be-

liefs that the earth's crust was solid and immoveable. One way around this problem was the suggestion that mammoth land bridges existed between continents. These large bridges would have allowed the movement of plants and animals from one continent to another. But no evidence for such bridges could be found, and this idea eventually fell into disrepute.

By the mid-1850s, an important breakthrough in geological thought began to occur. A few geologists started to accept the hypothesis that the earth's crust is not as solid and immovable as it appears. In fact, they said, it may be that the earth's outer layer is actually floating (and, thus, is moveable) on the layer below it, the mantle.

Still, it was not until the early years of the twentieth century that a new theory of "floating continents" was seriously proposed. Then, in a period of less than four years, two distinct theories of this kind were suggested. The first was offered in a December 29, 1908, paper by the American geologist Frank B. Taylor. Taylor outlined a theory that described how the continents had slowly shifted over time with a "mighty creeping movement."

Taylor's paper met largely with indifference. Such was not the fate, however, of the ideas of a German astronomer and meteorologist, Alfred Wegener. While browsing through the University of Marburg library in the fall of 1911, Wegener was introduced to the problem of continental similarities. Almost immediately, he decided to devote his attention to this question and began a study that was to dominate the rest of his professional life and to revolutionize the field of geology.

By January 1912, Wegener had developed a theory to explain continental similarities. Such similarities cannot be explained by sunken land bridges, he said, but are the result of continents having moved slowly across the face of the planet. Three more years of research were needed before Wegener's theory was completed. In 1915, he published *The Origins of Continents and Oceans*, summarizing his ideas about continental similarities.

According to Wegener's theory, the continents were once part of one large land mass, which he called Pangaea. Eventually this land mass broke into two parts, two supercontinents, which he called Gondwanaland and Laurasia. Over millions of years, Gondwanaland broke apart into South America, Africa, India, Australia, and **Antarctica**, he suggested, while Laurasia separated into North America and Eurasia.

The basic problem Wegener faced was to explain how huge land masses like continents can flow. His answer was that the materials of which the earth's crust is made are of two very different types. One, then call "sial," is relatively light, but strong. The other, then called "sima," can be compared to very thick tar. Continents are made of sial, he said, and sea floors of sima. The differences in these materials allows continents to "ride" very slowly across sea floors.

Wegener's theory was met with both rejection and hostility. Fellow scientists not only disagreed with his ideas, but also attacked him personally even for suggesting the ideas. The theory of continental drift did not totally disappear as a result of these attitudes, but it fell into disfavor for more than three decades.

Research dating to the mid-1930s revealed new features of the sea floor which made Wegener's theory more plausible. Scientists found sections of the ocean bottoms through which flows of hot lava were escaping from the mantle, somewhat like underwater volcanoes. These discoveries provided a crucial clue in the development of plate tectonics, the modern theory of continental drift.

According to the theory of plate tectonics, the upper layer of the earth is made of a number of plates, large sections of crust, and the upper mantle. About ten major plates have been identified. The largest plate is the Pacific Plate, underlying the Pacific Ocean. The North and South American, Eurasian, African, Indian, Australian, Nazca, Arabian, Caribbean, and Antarctica are the other major plates.

Scientists believe that plates rest on an especially plastic portion of the mantle known as the "asthenosphere." Hot magma from the asthenosphere seeps upward and escapes through the ocean floor by way of openings known as rifts. As the magma flows out of the rift, it pushes apart the plates adjoining the rift. The edge of the plate opposite the rift is ultimately forced downward, back into the asthenosphere. The region in which plate material moves down into the mantle is a trench.

Plates move at different speeds in different directions at different times. On an average, they travel 0.4–2 in (1-5 cm) per year. To the extent that this theory is correct, a map of the earth's surface ten million years from now will look quite different from the way it does now.

The theory of plate tectonics explains a number of natural phenomena that had puzzled scientists for centuries. Earthquakes, for example, can often be explained as the sudden, rather than gradual, movement of two adjacent plates. One of the world's most famous **earthquake** zones, the San Andreas Fault, lies at the boundary of the Pacific and the North American plates. Volcanoes often accompany the movement of plates and earthquakes. The boundaries of the Pacific Plate, for example, define a region where volcanoes are very common, a region sometimes called the Ring of Fire.

Plate tectonics is now accepted as one of the fundamental theories of geology. Its success depends not only on the discovery of an adequate explanation for continental movement (sea-floor spreading, rifts, and trenches), but also

on the discovery of more and more similarities between continents.

For example, modern geologists have re-examined Humboldt's ideas about the correlation of mountain ranges in South America and Africa. They have found that rock strata, or layers, in Brazil lie almost exactly where they should be expected if strata in Ghana are projected to the west. If the Atlantic Ocean could somehow be removed, the two strata could be made to coincide almost perfectly.

Some interesting data have come from studies of paleomagnetism also. Paleomagnetism refers to the orientation of iron crystals in very old rock. Since the earth's magnetic poles have shifted over time, so has the orientation of iron crystals in rock. Scientists have found that the orientation of iron crystals in one continent correspond very closely to those found in rocks of another continent thousands of miles away.

Fossils continue to be a crucial way of confirming continental drift. For example, scientists have learned that the fossil population of is much less like the fossil population of Africa (300 miles [483 km] to the west) than it is like the fossil population of India (3,000 miles/4,830 km to the northeast). This finding would make almost no sense at all unless one recognized that the theory of continental drift has **Madagascar** breaking off from India millions of years ago, not off Africa.

The flow of magma out of the asthenosphere often results in the formation of ores, regions that are rich in some mineral. For example, the high temperatures characteristic of a rift or a trench may be sufficient to cause the release of metals from their compounds. The flow of magma across rock may also result in a phenomenon known as contact metamorphism, a mechanism that also results in the formation of metals such as **lead** and silver. *See also* Biogeography; Endemic species; Evolution; Geosphere; Topography

Plow pan

A plow pan is a subsurface **horizon** or **soil** layer having a high **bulk density** and a lower total porosity than the soil directly above or below it as a result of pressure applied by normal tillage operations, such as plows, discs, and other tillage implements. Plow pans may also be called pressure pans, tillage pans, or traffic pans. Plow pans are not cemented by organic matter or **chemicals**. Plow pans are the result of pressure exerted by humans, whereas hard pans occur naturally. *See also* Soil compaction

Plume

A flowing, often somewhat conical, trail of emissions from a continuous **point source**, for example the plume of **smoke** from a chimney. As a plume spreads, its constituents are diluted into the surrounding medium. When plumes disperse in media with high turbulence, they can take on more complex shapes with loops and meanders. This somewhat chaotic nature has lead to probabilistic descriptions of the concentration of materials in plumes; for example, calculations concerning the downstream impact of pollutants released from pipes and chimneys will be couched in terms of average concentrations. Typically plumes are found in air or water, but plumes of trace contaminants may also be found in less-mobile media such as soils.

Plutonium

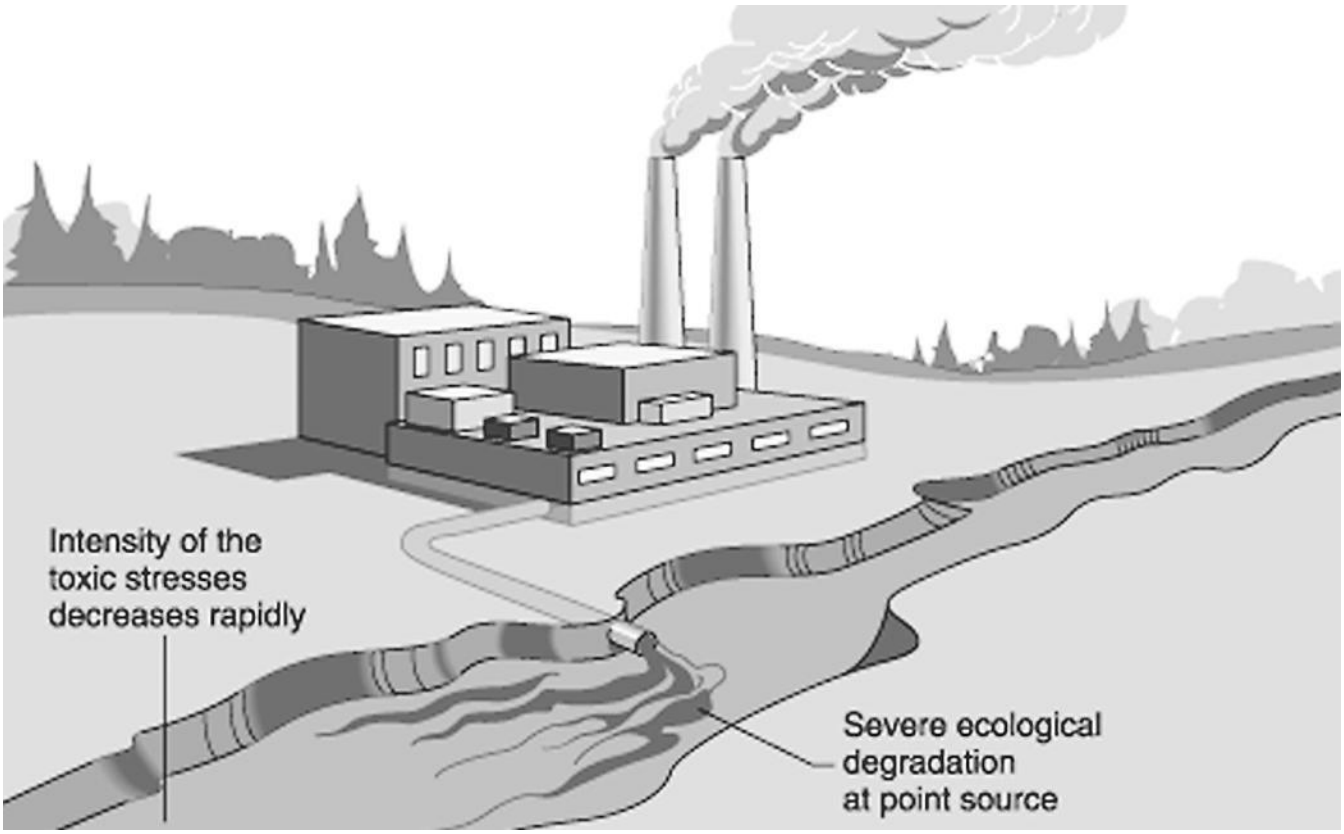
A synthetically produced transuranium element. It does not exist in measurable amounts in the earth's crust. Glenn Seaborg and his colleagues at the University of California at Berkeley first prepared this element in 1940. Plutonium is by far the most important of all transuranium elements because one of its isotopes, plutonium-239, can be fissioned. Plutonium-239 is the only **isotope** other than uranium-235 that is readily available for use in **nuclear weapons** and nuclear reactors. Unfortunately plutonium is also one of the most toxic substances known to humans, making its commercial use a serious environmental hazard. With a **half-life** of 24,000 years, the isotope presents difficult disposal problems. *See also* Nuclear fission; Nuclear power

Poaching

Poaching is the stealing of game or fish from private property or from a place where shooting, **trapping** or fishing rights are reserved. Until the twentieth century, most poaching was subsistence **hunting** or fishing to augment scanty diets. Today, poaching is usually committed for sport or profit.

The **Fish and Wildlife Service** estimates that illegal trade in U.S. **wildlife** generates $200 million per year, a hefty slice of a $1.5 billion worldwide market. Big game animals are shot as trophies, and animal parts such as bear

A poached rhinoceros with its horn removed. (Photograph by Warren and Jenny Garst. Tom Stack & Associates. Reproduced by permission.)



gallbladders are sold for "medicinal" purposes--usually as tonics to enhance male virility. Poaching also attracts organized crime because wildlife crime sentences, if tendered, tend to be lenient and probation requirements are difficult to enforce.

Poaching has a long history in this country: spotlighting a deer at night or shooting a duck in the family pond for dinner have long been a part of rural life. Today, despite a 94 percent conviction rate for those caught, poachers feed a demand for wildlife on both domestic and global markets. They decapitate walruses for ivory tusks, net thousands of night-roosting robins for Cajun gumbo, and shoot anhingas nesting in the **Everglades** and raptors for decorative feathers. **Wolves** are tracked and shot from airplanes. Sturgeon and paddlefish are caught and killed for their caviar. Poaching poses a serious threat to wildlife because it kills off the biggest and best of a species' **gene pool**. A report by the Fish and Wildlife Service estimates that 3,600 threatened or **endangered species** receive little or no federal protection.

The **extinction** of the Labrador duck in the 1880s and the near extinction of a dozen other waterfowl **species** led to the U.S.-Canadian Migratory Bird Treaty Act of 1918. The enactment of kill limits and the ban on commercial market hunting helped populations of birds. The U.S. Marine Mammal Protection Act of 1972 makes it a crime for non-Native Americans to hunt or sell walruses, sea otters, **seals and sea lions**, and polar bears. And the Lacey Act, passed in 1990, makes it a federal crime to transport illegally taken wildlife across state lines.

The sale of bear parts is legal in some states, creating a convenient outlet for poachers. Since merchandise such as bear meat, galls, and paws is difficult to track, the poachers are fairly safe. Uniform regulations in all 50 states would create a more difficult **environment** for poachers to operate in and might lead to a decrease in poaching, especially of bears.

As economic and political instability increased in many developing countries, so did poaching. A global demand for ivory caused wholesale slaughter of **elephants** and rhinoc-

An example of a point source.

eros. As the big male elephants disappeared, poachers turned to females, the primary caretakers of the young. To help stop the carnage of elephant and rhinoceros for their ivory, 105 nations party to the **Convention on International Trade in Endangered Species of Wild Fauna and Flora** (CITES) have agreed to ban the raw ivory trade. The ban has caused ivory prices to plummet to pre-1970s levels, making poaching much less attractive. In Zimbabwe, game wardens now also have orders to shoot on sight poachers who menace the rare black rhino. *See also* Grizzly bear

Point source

A localized, discrete, and fixed contaminant **emission** source, such as a smokestack or waste **discharge** pipe. Since point sources are usually easily identified, their discharges of **pollution** can be monitored readily. Point sources are distinguished from nonpoint sources and mobile (or vehicular) sources and historically were the first to receive emission controls. Some point sources release exceptionally large quantities of contaminants. For example, a **smelter** in **Sudbury, Ontario**, was for many years the largest single source of **sulfur dioxide** in North America, emitting several million tons of pollutants annually through a smokestack over 1,247 ft (380 m) tall.

Poisoning

Poisoning, either from naturally occurring or manmade **chemicals**, can result from ingestion, inhalation, or skin contact with the toxin. It can also be either acute (a one-time, high amount such as a drug overdose) or chronic (a smaller, amount over a long period of time, such as **lead** poisoning). Poison control centers in many countries can provide information on treatment and prevention of accidental poisoning from household or industrial products. There are more than 13 million known **toxins**, but less than 3,000 cause most incidents of poisoning. Several practices put in place since the 1950's have reduced accidental poisoning by ten-fold. These practices include the accurate labeling of potentially poisonous household compounds, and the use of monitoring devices such as carbon-monoxide detectors. One of the most successful prevention tactics is the use of child-resistant caps on containers of medicine and household products.

[*Marie H. Bundy*]

Pollination

Pollination is the process of moving pollen grains, which contain male sex cells, from the anthers (the pollen-containing part of floral stamens, the male reproductive structure) of flowers to the stigma (the glandular female receptive portion) in the pistil (female reproductive organ). When a pollen grain lands on the female part of the flower, the male sex cell joins with the female sex cells in the flower in a process called fertilization to form a seed from which a new plant can grow. The anthers and stigma can be on the same flower (self-pollination) or on different flowers (cross-pollination), but must be of the same **species**. All higher plants, including flowers, herbs, bushes, grasses, conifers, and broad-leaved trees, use pollination for sexual reproduction.

Pollination can be accomplished by abiotic means such as wind and water. Many pollen grains are small (less than 0.05 mm, or 0.002 in). Thus wind can carry the pollen grains to other members of their species. Many plants, to ensure pollination, grow in dense stands and produce millions of pollen grains. Wind-pollinated plants generally have small, inconspicuous flowers that dangle in the wind (e.g., willow catkins). Grasses have wispy plume-like flowers that catch grains floating in the air. Some water plants such as the hornwort have their pollen transferred by water currents.

Many plants use animals such as insects, birds, and **bats** to transport pollen grains. This process, referred to as biotic pollination, requires a relationship between the pollinator and the flower to be pollinated. Such a relationship is usually established by some kind of direct attractant, such as nectar, sweet-tasting pollen, odor, or visual attraction (e.g., brightly-colored flowers). There may also be an indirect attraction, such as when insects of prey visit flowers to catch other visiting pollinators.

Insects, including bees, beetles, flies, wasps, ants, butterflies, and moths, are common biotic pollinators. As an insect crawls in and out of flowers in its search for nectar or other food source, it receives a dusting of pollen grains from the anther, the male part. When the insect visits another flower, the pollen rubs off on the stigma, the female part. If the pollen is left on the same species of flower, a long tube grows from each pollen grain down the stalk (style) of the stigma and into the ovule at the base, which contains the female egg cells. The male cells from the pollen grains pass along the tubes to the female cells and fertilize them. Plants with trumpet-shaped flowers, such as petunias, have nectar at the bottom, so only insects with long tube-like tongues can act as their pollinators.

The best-known and best-adapted biotic pollinator is the bee. The bee is a relatively large insect with a large demand for food both for itself and for its carefully looked-after brood. It normally gets all of its food from flower blossoms. The bee has an ability to remember plant forms, which aids in its ability to find flowers. Social bees live together in a communal nest and often share foraging and nest activities. The amount of food carried into a hive by a honeybee has been estimated to be 100 times its own requirements. Social bees have developed communication systems that permit them to inform each other about the location and sources of food. These communication systems include odor paths, special buzz tones to alert other individuals, and dances that can indicate direction, distance to, and yield of a source of food. However, most of the world's 40,000 species of bees are solitary. The female bee mates and then constructs a nest underground or within woody stems containing many smooth-walled cells. The cells are filled with a mixture of nectar and pollen, which provides all the food required for larvae to complete their development into adult bees.

Biotic pollination may also be accomplished by such animals as birds and bats. For example, hummingbirds feeding from the hibiscus flower carry pollen on their beak and heads. Bats hover in front of flowers that open at night, licking nectar and covering their faces with pollen. Successful pollination, often mediated by animals but also accomplished abiotically, is extremely important for food production as well as maintenance of biological plant diversity. Pollination of plants is necessary for seed set, fruit yields, and reproduction of most food crops.

Many threats to animal pollinators and pollination processes have been identified. These include use of toxic **chemicals**, decline in pollinator populations, **habitat** loss, and migratory corridor fragmentation. Toxic chemicals can kill

pollinators, and wild pollinators are often more vulnerable to insecticides and herbicides than domestic honeybees. Laws regulate and control the use of many pesticides during periods when pollinators are foraging, and use of toxic chemicals near pollinators' nesting sites should also be controlled. Pesticides that are known to be less toxic to pollinators can be used to reduce stress on pollinator populations. Fewer pollinators will result in fewer plants. When factors such as the use of pesticides and **habitat fragmentation** reduce populations of pollinators, plants will have low reproductive success. Some endangered plant species may even become extinct. Appropriate **pesticide** spraying set-back distances should be based on on-site determinations made by pollination ecologists familiar with the plant and pollinator species involved.

Another threat to pollination processes is the decline in honeybee populations. Since 1990, U.S. beekeepers have lost one-fifth of their domestic managed honeybee colonies for reasons that include two kinds of mite infestations, diseases, spraying of pesticides, and several other factors. The *Varroa* mite is an external parasite that was identified in the United States in 1987 and affects bee colonies in thirty states. This mite lives and feeds on developing bee larvae so that when the bees hatch, they are small and deformed. *Varroa* mites can be controlled by placing medicated plastic strips inside hives to kill the mites. The bees walk on the strips and then carry the medicine on their feet to the larvae growing in the honeycomb. The tracheal mite infects the respiratory system of adult honeybees. These mites were found in the United States in 1984 and are now present in most states. These tracheal mites make bees weak and can kill an entire colony. To control the mites, an antibiotic powder, such as terramycin, is mixed into sugar and oil and is placed inside the bee hive.

Diseases and use of pesticides also take their toll on bee populations. There are several diseases that can kill bees; these include American foul brood, chalk brood, European foul brood, paralysis **virus**, sacbrood disease and kashmir virus. Some bacterial diseases can be treated by stirring antibiotics into feed sugar. Often, if a hive is badly infected, the hive is burned to prevent the infection of other hives. Also, the spraying of pesticides (e.g., by farmers for crop protection or by towns and communities for control of mosquitoes) when bees are foraging can result in their death. Some pesticides kill bees directly while they are in the crops, while others are carried back to the hives with the pollen, where they are stored in the honeycombs. The bees and larvae die when they eat the pollen, which can be at any time of year. Often the pesticide does not kill the entire colony, but makes the colony susceptible to mite infections or freezing in cold weather.

Several other factors have contributed to declining bee populations. **Africanized bees**, a type of highly defensive bee that is also known as the killer bee, became established in the United States in 1990, after years of northward **migration** from South America where they were first released. Beekeepers often are forced to abandon their hives when Africanized bees move into an area. Also, bee populations that have been weakened by other factors are in danger of freezing in winter, due to an insufficient number of bees to provide necessary warmth; or an insufficient supply of food to convert to heat energy. Finally, loss of agricultural subsidies and price supports in the United States adversely affects the economics of managing bee colonies.

Habitat loss and the severing of migratory corridors also constitute threats to animal pollinators and pollination processes. Habitat fragmentation is the division of natural ecosystems into smaller areas due to land conversion for agriculture, forestry, and urbanization. As habitat areas become smaller and widely scattered, they may be insufficient to provide an adequate diversity of host plants and nectar sources that their pollinators require. Habitat fragmentation may also cause reduction in pollinator populations due to loss of nesting habitats. Ecologists need to monitor populations of pollinators and habitat fragmentation trends to determine possible causes of pollinator decline and to develop **land use** plans to protect pollinator populations such as maintenance of habitat set-asides or greenbelts near agricultural fields and timber areas.

The severing of migratory corridors can also disrupt pollination processes. Some pollinating animal species, such as nectarivorous bats, navigate through a variety of nectar-providing plants as they migrate from tropical to **arid** and temperate environments. A bat species may utilize a single type of flower in each local **environment**, but a series of plants are linked into a nectar corridor of successive flowering times along the bat's migration route. For example, a type of long-nosed bat flies a loop of 3,200 mi (5,152 km) to follow the sequential flowering of at least 16 flowering plants species, including tree morning glories, several century plants, and giant columnar cactus. Severing of migratory corridors by habitat and vegetation destruction or by spraying of toxic pesticides may adversely affect the success of the migration. For example, migratory monarch butterflies require critical habitats through their migratory cycle and can be affected if habitat is lost due to activities such as development. Monitoring of plant/pollinator changes in migratory corridors is required to develop appropriate protection strategies.

Pollution

Pollution can be defined as unwanted or detrimental changes in a natural system. Usually, pollution is associated with the presence of toxic **chemicals** in some large quantity, but pollution can also be caused by the presence of excess quantities of heat or by excessive fertilization with nutrients.

Because pollution is judged on the basis of degradative changes, there is a strongly anthropocentric bias to its determination. In other words, humans decide whether pollution is occurring and how bad it is. Of course, this bias favors **species**, communities, and ecological processes that are especially desired or appreciated by humans. In fact, however, some other, *less-desirable* species, communities, and ecological processes may benefit from what we consider pollution.

An important aspect of the notion of pollution is that ecological change must actually be demonstrated. If some potentially polluting substance is present at a concentration or intensity that is less than the threshold required to cause a demonstrable ecological change, then the situation would be referred to as contamination, rather than pollution.

This aspect of pollution can be illustrated by reference to the stable elements, for example, **cadmium**, **copper**, **lead**, **mercury**, **nickel**, selenium, **uranium**, etc. All of these are consistently present in at least trace concentrations in the **environment**. Moreover, all of these elements are potentially toxic. However, they generally affect biota and therefore only cause pollution when they are present at water-soluble concentrations of more than about 0.01 to 1 **parts per million** (ppm).

Some other elements can be present in very large concentrations, for example, **aluminum** and iron, which are important constituents of rock and **soil**. Aluminum constitutes 8-10 percent of the earth's crust and iron 3-4 percent. However, almost all of the aluminum and iron present in minerals are insoluble in water and are therefore not readily assimilated by **biotic community** and cannot cause toxicity. In acidic environments, however, ionic forms of aluminum are solubilized, and these can cause toxicity in concentrations of less than one part per million. Therefore, the bio-availability of a chemical is an important determinant of whether its presence in some concentration will cause pollution.

Most instances of pollution result from the activities of humans. For example, **anthropogenic** pollution can be caused by:

- the **emission** of **sulfur dioxide** and metals from a **smelter**, causing toxicity to vegetation and acidifying surface waters and soil,
- the emission of waste heat from an electricity generating station into a river or lake, causing community change through thermal stress, or
- the **discharge** of nutrient-containing sewage wastes into a water body, causing eutrophication.

Most instances of anthropogenic pollution have natural analogues, that is, cases where pollution is not the result of human activities. For example, pollution can be caused by the emission of sulfur dioxide from volcanoes, by the presence of toxic elements in certain types of soil, by thermal springs or vents, and by other natural phenomena. In many cases, natural pollution can cause an intensity of ecological damage that is as severe as anything caused by anthropogenic pollution. (This does not, of course, in any way justify anthropogenic pollution and its ecological effects.)

An interesting case of natural **air pollution** is the Smoking Hills, located in a remote and pristine **wilderness** in the Canadian Arctic, virtually uninfluenced by humans. However, at a number of places along the 18.63 miles (30 km) of seacoast, bituminous shales in sea cliffs have spontaneously ignited, causing a **fumigation** of the **tundra** with sulfur dioxide and other pollutants. The largest concentrations of sulfur dioxide (more than two parts per million) occur closest to the combustions. Further away from the sea cliffs the concentrations of sulfur dioxide decrease rapidly. The most-important chemical effects of the air pollution are **acidification** of soil and fresh water, which in turn causes a solubilization of toxic metals. Surface soils and pond waters commonly have pHs less than 3, compared with about **pH** 7 at non-fumigated places. The only reports of similarly acidic water are for volcanic lakes in Japan, in which natural pHs as acidic as 1 occur, and pH less than 2 in waters affected by **drainage** from **coal** mines.

At the Smoking Hills, toxicity by sulfur dioxide, acidity, and water-soluble metals has caused great damage to ecological communities. The most-intensively fumigated terrestrial sites have no vegetation, but further away a few pollution-tolerant species are present. About one kilometer away the toxic stresses are low enough that reference tundra is present. There are a few pollution-tolerant algae in the acidic ponds, with a depauperate community of six species occurring in the most-acidic (pH 1.8) pond in the area.

Other cases of natural pollution concern places where certain elements are present in toxic amounts. Surface mineralizations can have toxic metals present in large concentrations, for example copper at 10 percent in peat at a copper-rich spring in New Brunswick, or surface soil with three percent lead plus zinc on Baffin Island. Soils influenced by nickel-rich serpentine minerals have been well-studied by ecologists. The stress-adapted plants of serpentine habitats form distinct communities, and some plants can have nickel concentrations larger than 10 percent in their tissues. Simi-

larly, natural soils with large concentrations of selenium support plants that can hyperaccumulate this element to concentrations greater than one percent. These plants are poisonous to livestock, causing a toxic syndrome known as *blind staggers*.

Of course, there are many well-known cases where pollution is caused by anthropogenic emissions of chemicals. Some examples include:

- Emissions of sulfur dioxide and metals from smelters can cause damage to surrounding terrestrial and aquatic ecosystems. The sulfur dioxide and metals are directly toxic. In addition, the deposition of sulfur dioxide can cause an extreme acidification of soil and water, which causes metals to be more bio-available, resulting in important, secondary toxicity. Because smelters are point sources of emission, the spatial pattern of chemical pollution and ecological damage displays an exponentially decreasing intensity with increasing distance from the source.
- The use of pesticides in agriculture, forestry, and around homes can result in a non-target exposure of birds and other **wildlife** to these chemicals. If the non-target biota are vulnerable to the **pesticide**, then ecological damage will result. For example, during the 1960s urban elm trees in the eastern United States were sprayed with large quantities of the insecticide DDT, in order to kill beetles that were responsible for the transmission of Dutch elm disease, an important **pathogen**. Because of the very large spray rates, many birds were killed, leading to reduced populations in some areas. (This was the "silent spring" that was referred to by Rachel Carson in her famous book by that title.) Birds and other non-target biota have also been killed by modern insecticide-spray programs in agriculture and in forestry.
- The deposition of acidifying substances from the **atmosphere**, mostly as acidic precipitation and the **dry deposition** of sulfur dioxide, can cause an acidification of surface waters. The acidity solubilizes metals, most notably aluminum, making them bio-available. The acidity in combination with the metals causes toxicity to the biota, resulting in large changes in ecological communities and processes. Fish, for example, are highly intolerant of acidic waters.
- Oil spills from tankers and pipelines can cause great ecological damage. When oil spilled at sea washes up onto coastlines, it destroys seaweeds, invertebrates, and fish, and their communities are changed for many years. Seabirds are very intolerant of oil and can die of hypothermia if even a small area of their feathers is coated by petroleum.
- Most of the **lead shot** fired by hunters and skeet shooters miss their target and are dispersed into the environment. Waterfowl and other avian wildlife actively ingest lead shot because it is similar in size and hardness to the grit that they ingest to aid in the mechanical abrasion of hard seeds in their gizzard. However, the lead shot is toxic to these birds, and each year millions of birds are killed by this source in North America.

Humans can also cause pollution by excessively fertilizing natural ecosystems with nutrients. For example, freshwaters can be made eutrophic by fertilization with **phosphorus** in the form of phosphate. The most conspicuous symptoms of eutrophication are changes in species composition of the **phytoplankton** community and, especially, a large increase in algal **biomass**, known as a *bloom*. In shallow waterbodies there may also be a vigorous growth of vascular plants. These primary responses are usually accompanied by secondary changes at higher trophic levels, including arthropods, fish, and waterfowl, in response to greater food availability and other **habitat** changes. However, in the extreme cases of very eutrophic waters, the blooms of algae and other **microorganisms** can be noxious, producing toxic chemicals and causing periods of oxygen depletion that kill fish and other biota. Extremely eutrophic waterbodies are polluted because they often cannot support a fishery, cannot be used for drinking water, and have few recreational opportunities and poor esthetics.

Pollution, therefore, is associated with ecological degradation, caused by environmental stresses originating with natural phenomena or with human activities. The prevention and management of anthropogenic pollution is one of the greatest challenges facing modern society. *See also* Cultural eutrophication

Pollution control

Pollution control is the process of reducing or eliminating the release of pollutants into the **environment**. It is regulated by various environmental agencies which establish pollutant **discharge** limits for air, water, and land.

Air pollution control strategies can be divided into two categories, the control of **particulate** emissions and the control of gaseous emissions. There are many kinds of equipment which can be used to reduce particulate emissions. Physical separation of the particulates from the air using settling chambers, **cyclone** collectors, impingers, wet

scrubbers, electrostatic precipitators, and **filtration** devices, are all processes that are typically employed.

Settling chambers use gravity separation to reduce particulate emissions. The air stream is directed through a settling chamber, which is relatively long and has a large cross section, causing the velocity of the air stream to be greatly decreased and allowing sufficient time for the settling of solid particles.

A **cyclone collector** is a cylindrical device with a conical bottom which is used to create a tornado-like air stream. A centrifugal force is thus imparted to the particles, causing them to cling to the wall and roll downward, while the cleaner air stream exits through the top of the device.

An impinger is a device which uses the inertia of the air stream to impinge mists and dry particles on a solid surface. Mists are collected on the impinger plate as liquid forms and then drips off, while dry particles tend to build up or reenter the air stream. It is for this reason that liquid sprays are used to wash the impinger surface as well, to improve the collection efficiency.

Wet scrubbers control particulate emissions by wetting the particles in order to enhance their removal from the air stream. Wet scrubbers typically operate against the current by a water spray contacting with the gas flow. The particulate matter becomes entrained in the water droplets, and it is then separated from the gas stream. Wet scrubbers such as packed bed, venturi, or plate scrubbers utilize initial impaction, and cyclone scrubbers use a centrifugal force.

Electrostatic precipitators are devices which use an electrostatic field to induce a charge on dust particles and collect them on grounded electrodes. Electrostatic precipitators are usually operated dry, but wet systems are also used, mainly by providing a water mist to aid in the process of cleaning the particles off the collection plate.

One of the oldest and most efficient methods of particulate control, however, is filtration. The most commonly-used filtration device is known as a **baghouse** and consists of fabric bags through which the air stream is directed. Particles become trapped in the fiber mesh on the fabric bags, as well as the filter cake which is subsequently formed.

Gaseous emissions are controlled by similar devices and typically can be used in conjunction with particulate control options. Such devices include scrubbers, **adsorption** systems, condensers, flares, and incinerators.

Scrubbers utilize the phenomena of adsorption to remove gaseous pollutants from the air stream. There is a wide variety of scrubbers available for use, including spray towers, packed towers, and venturi scrubbers. A wide variety of solutions can be used in this process as absorbing agents. Lime, magnesium oxide, and sodium hydroxide are typically used.

Adsorption can also be used to control gaseous emissions. Activated **carbon** is commonly used as an adsorbent in configurations such as fixed bed and fluidized bed adsorbers.

Condensers operate in a manner so as to condense vapors by either increasing the pressure or decreasing the temperature of the gas stream. Surface condensers are usually of the shell-and-tube type, and contact condensers provide physical contact between the vapors, coolant, and condensate inside the unit.

Flaring and **incineration** take advantage of the combustibility of a gaseous pollutant. In general, excess air is added to these processes to drive the **combustion** reaction to completion, forming **carbon dioxide** and water.

Another means of controlling both particulate and gaseous air pollutant **emission** can be accomplished by modifying the process which generates these pollutants. For example, modifications to process equipment or raw materials can provide effective source reduction. Also, employing fuel cleaning methods such as desulfurization and increasing fuel-burning efficiency can lessen air emissions.

Water pollution control methods can be subdivided into physical, chemical, and biological treatment systems. Most treatment systems use combinations of any of these three technologies. Additionally, **water conservation** is a beneficial means to reduce the volume of **wastewater** generated.

Physical treatment systems are processes which rely on physical forces to aid in the removal of pollutants. Physical processes which find frequent use in water pollution control include screening, filtration, **sedimentation**, and **flotation**. Screening and filtration are similar methods which are used to separate coarse solids from water. Suspended particles are also removed from water with the use of sedimentation processes. Just as in **air pollution** control, sedimentation devices utilize gravity to remove the heavier particles from the water stream. The wide array of sedimentation basins in use slow down the water velocity in the unit to allow time for the particles to drop to the bottom. Likewise, flotation uses differences in particle densities, which in this case are lower than water, to effect removal. Fine gas bubbles are often introduced to assist this process; they attach to the particulate matter, causing them to rise to the top of the unit where they are mechanically removed.

Chemical treatment systems in water pollution control are those processes which utilize chemical reactions to remove water pollutants or to form other, less toxic, compounds. Typical chemical treatment processes are chemical precipitation, adsorption, and disinfection reactions. Chemical precipitation processes utilize the addition of **chemicals** to the water in order to bring about the precipitation of **dissolved solids**. The solid is then removed by a physical process such as sedimentation or filtration. Chemical precip-

itation processes are often used for the removal of **heavy metals** and **phosphorus** from water streams. Adsorption processes are used to separate soluble substances from the water stream. Like air pollution adsorption processes, activated carbon is the most widely used adsorbent. Water may be passed through beds of granulated activated carbon (GAC), or powdered activated carbon (PAC) may be added in order to facilitate the removal of dissolved pollutants. Disinfection processes selectively destroy disease-causing organisms such as bacteria and viruses. Typical disinfection agents include **chlorine**, **ozone**, and **ultraviolet radiation**.

Biological water pollution control methods are those which utilize biological activity to remove pollutants from water streams. These methods are used for the control of **biodegradable** organic chemicals, as well as nutrients such as **nitrogen** and phosphorus. In these systems, **microorganisms** consisting mainly of bacteria convert carbonaceous matter as well as cell tissue into gas. There are two main groups of microorganisms which are used in biological treatment, **aerobic** and **anaerobic** microorganisms. Each requires unique environmental conditions to do its job. Aerobic processes occur in the absence of oxygen. Both processes may be utilized whether the microorganisms exist in a suspension or are attached to a surface. These processes are termed suspended growth and fixed film processes, respectively.

Solid pollution control methods which are typically used include landfilling, **composting**, and incineration. Sanitary landfills are operated by spreading the **solid waste** in compact layers which are separated by a thin layer of **soil**. Aerobic and anaerobic microorganisms help to break down the biodegradable substances in the **landfill** and produce carbon dioxide and **methane** gas which is typically venter to the surface. Landfills also generate a strong wastewater called leachate which must be collected and treated to avoid **groundwater** contamination.

Composting of solid wastes is the microbiological biodegradation of organic matter under either aerobic or anaerobic conditions. This process is most applicable for readily biodegradable solids such as sewage **sludge**, paper, **food waste**, and household **garbage**, including garden waste and organic matter. This process can be carried out in static pile, agitated beds, or a variety of reactors.

In an incineration process, solids are burned in large furnaces thereby reducing the volume of solid wastes which enter landfills, as well as reducing the possibility of groundwater contamination. Incineration residue can also be used for metal **reclamation**. These systems are typically supplemented with air pollution control devices. *See also* Air pollution index; Air quality criteria; Clean Air Act; Clean Water Act; Emission standards; Heavy metals and heavy metal poisoning; Industrial waste treatment; Primary standards; Secondary standards; Sewage treatment; Water quality standards

Pollution credits

Pollution credits emerged from the federal **Clean Air Act** of 1990 (CAA) as a way for businesses to deal with the regulations that attempt to lower **air pollution**. The **Environmental Protection Agency** (EPA) and individual states have created a "cap and trade" system (in practice since 1995) allowing utilities and manufacturers allowances to emit a certain amount of specific pollutants. This system offers companies some flexibility in their compliance while helping to maintain the standards required for cleaner air.

A company can earn pollution credits by voluntarily reducing polluting emissions below limits dictated by the EPA. Earned credits can then be sold to another company that has trouble keeping its emissions within permissible limits, or saved for future use. According to Dean S. Sommer writing for *The Albany (New York) Business Review* in March 1999, "The 'cap' portion of the system refers to the specific amount of emissions that may be discharged within a state, region or the nation as set forth by the EPA and the CAA. The 'trade' portion refers to a participant's ability to buy or sell the allowances. States, or the EPA, allocate **emission** allowances to affected sources in specified amounts to ensure that the cap is not exceeded by emissions from all participants."

Different "cap and trade" allowances apply to the most common pollutants, **sulfur dioxide** and **nitrogen oxides**, which contribute to **acid rain**, **smog**, and **ozone** depletion. Each allowance, or credit, is a trading unit equivalent to one ton of air emissions. The EPA exacts annual penalties to those companies whose emissions exceed the number of allowances.

According to the EPA, the practice of pollution credits bartering has proven beneficial not only in reducing air pollution, but in providing an incentive for companies to meet

environmental goals. For example, the EPA's national **acid** rain program to reduce sulfur dioxide resulted in a decrease of six million tons of emissions a year compared to 1980 levels. **Nitrogen** oxide levels were reduced by 50% compared to 1990 levels as a result of a program undertaken by numerous northeastern states.

Critics of the trading program, however, have suggested that the system is flawed. They contend that although it was meant to be a way of encouraging industry to find ways of producing less pollution, the system provides a way of merely transferring responsibility—the one polluting is not held responsible for the poor quality of air it has affected.

In 2000, for example, the state of New York identified several midwestern and southeastern states—Delaware, Illinois, Indiana, Ohio, Michigan, Kentucky, Maryland, New Jersey, North Carolina, Pennsylvania, Tennessee, Virginia, West Virginia, and Wisconsin—as the major sources of its acid rain, a serious problem undermining **natural resources** and **wildlife**. Between 1995 and 2000, the state had accumulated more than 700,000 pollution credits—providing the New York businesses selling them with a total of approximately $37.5 million. The result was that pollution within New York had declined only to be blown back over state lines by other states that had purchased the credits. According to a May 2, 2000 report of the *Environment News Service* (ENN) by writer Cat Lazaroff, "Despite the state's efforts to reduce sulfur dioxide emissions, many high altitude lakes in New York's **Adirondack Mountains** remain too acidic to support many native **species**. Some government studies estimate about half of the region's 3,000 lakes and ponds may become too acidic to support life if acid rain is not reduced." The state fought back with legislation authorizing the fining of utility companies that sell their pollution credits to the polluting states.

Attempts to regulate less and provide more incentives have been met with suspicion by program critics, who fear an increase in pollution, and applause by businesses, who view the reduction in standards as a possible financial relief. In any case, pollution credits had become a valuable commodity on the open market by the early twenty-first century, in the United States and throughout the world.

Pollution Prevention Act (1990)

The **Pollution** Prevention Act of 1990 is a piece of legislation intended to limit the creation of pollution. As part of the Omnibus Budget Reconciliation Act of 1990, the Pollution Prevention Act differed from previous legislation, which had generally treated pollution after it had been created. **Environmental Protection Agency** (EPA) administrator William K. Reilly strongly supported the act, believing that much hazardous or toxic pollution can be more effectively and economically controlled, and the **environment** protected more fully, if the pollution never occurs.

The impetus for this act lies in a 1986 EPA report to Congress entitled "Minimization of Hazardous Wastes." Based on this report, the agency began to take actions designed to reduce pollution. According to a subsequent report by the Office of Technology Assessment (OTA), however,

the EPA needed to do more. The two reports identified four main approaches to prevent pollution: (1) manufacturing changes, (2) equipment changes, (3) product reformulations and substitutions, and (4) improved industrial housekeeping. By using such approaches, companies (and individuals) can both save money by reducing **pollution control** costs and have a cleaner environment because certain pollution will be prevented. The corporation 3M, for instance, has saved over $300 million since 1975 by reducing air, water, and **sludge** pollutants at the source. The OTA estimated that a ten percent reduction in hazardous wastes per year for five years could be achieved through source reduction. The reports also found that pollution prevention is primarily hindered not by a lack of technology but rather by a lack of knowledge and awareness due to institutional hurdles. The Pollution Prevention Act was designed to help overcome these hurdles through information collection, assistance in technology transfer, and financial assistance to state pollution prevention programs.

In addition to developing a general strategy to promote the reduction of pollution at its source, the act crated a new EPA office to administer the program. The major provisions of the law are as follows: a state grant program to aid states in establishing similar pollution prevention programs; EPA technical assistance for business; the development of a Source Reduction Clearinghouse, administered by the EPA and available for public use, to help in the collection and distribution of source reduction information; the establishment of an advisory committee on the issue; the creation of a training program on pollution prevention; and the creation of annual awards to businesses that achieve outstanding source reduction. Businesses using toxic substances were required to meet special standards--to report on how many and the amount of toxic substances released into the environment, how much recycled, how they attempted to prevent the generation of toxic pollutants, and how they learned of source reduction techniques. Lastly, the EPA is to report biennially on the effectiveness of the new program and its components. The Act authorized $16 million each year for three years for the EPA to implement this program.

Nicholas Polunin (1909 – 1997)

English environmentalist

Nicolas Polunin will be long remembered for two unusual achievements. First, he founded and was first editor of not one but two influential journals, *Biological Conservation* (founded in 1967 and edited from that year to 1974) and then *Environmental Conservation* (founded in 1974 and edited from its inception through 1995 when he was in his mid-eighties). Second, the readers of either journal, but particularly the latter, will remember the vivid language Polunin used in numerous editorials and other articles and texts to urge readers to start paying attention to the impact of human activities on other species on earth and on the natural environment.

Polunin credited his very public concern about such issues to a small UNESCO Conference in Finland in 1966, where he "had a sudden realization, amounting to a kind of vision, that if the world's populations went on growing and acting as profligately as they had been doing in recent decades, more and more ecodisasters would be inevitable and ultimately there would be an end to much of what was best in our civilization and conceivably to all life on Earth." He went on to say that "thereupon we decided that it was our solemn duty to do all we could henceforth to warn humanity of these grave dangers." That "quite shocking realization" led to his founding and editing of the international journal on conservation, and after he considered it "sufficiently established," a "more predominately environmental journal." *Biological Conservation* has become a mainstay for scientists investigating the vast range and significance of biological diversity on the planet and on the possibilities for sustainable use by humans of the biosphere. *Environmental Conservation* tries to reach a wider readership, one well outside the community of research biologists and is much more activist in tone and content. Establishment of two such influential journals is a significant accomplishment and they remain Polunin's enduring legacy, one matched by few other ecologists.

On the cover of the first issue of *Biological Conservation*, Polunin listed 30 subject headings as "the content of our subject." These included the history and development of conservation, a focus on "man and environment," disturbance and maintenance of ecosystems and the biosphere, population dynamics, threatened species and nature reserves and

parks, legislation and enforcement, education and training, fresh waters and wetlands, and a list of chemical, physical and biological threats to wildlife and environment. Those 30 topics were listed only on the first six issues, but the editorial description of topics for papers (as noted on an inside cover sheet in most science journals) are almost identical in the latest issues (2002) with those Polunin stated in the first issue. Typically, however, Polunin's topical editorial in that first issue was titled "Some Warnings," suggesting that "our world is beset with many threats," including his concern about the rapid increase in human population, a concern he voiced many times in editorials in both journals. In a still relevant and prescient voice, he called for a "severe limitation of human breeding and cognate desecrating tendencies." When he stepped down as editor, the publishers noted his energy and enthusiasm as reflected in "the great wealth of material published under his guidance."

While the stated purpose in the first journal was, and remains, the widest possible dissemination of original papers on "the preservation of wildlife and all nature," Polunin's editorial directions to authors in the first issue of *Environmental Conservation* differed quite radically, stating that the journal "advocates timely action for the protection and amelioration of the environment of Man and Nature throughout the world...for the lasting future of Earth's fragile biosphere." Polunin's editorial language remained strong, continuing to warn about the plagues human actions were visiting on each other, on other organisms, and on the earth. Words and phrases like 'faustian bargain,' 'ecodisasters,' 'our world menaced' and 'rays of hope' were common in his editorial pleas for sanity.

He published longer statements, such as his "Thoughts on Some Conceivable Ecodisasters" in the Autumn, 1974, issue of *Environmental Conservation*, he organized major international conferences on the environmental future and edited the proceedings, all evidence of his world-wide influence on thinking about human-environment issues and problems. He also never lost hope, claiming in 1991 (Autumn issue of *Environmental Conservation*) that there had been "recent changes for the better in the prospect of an improved future for the global environment" and listing twelve rays of hope, including "a growing realization that there are coming to be far too many human beings on our limited Planet Earth."

Nicholas Polunin was born in England to a Russian father and an English mother. He earned a First Class Honours degree in botany and ecology from Oxford in 1932, a Masters from Yale, and returned to Oxford for a PhD in 1935. One of his mentors was Arthur Tansley. He traveled widely with a number of scientific expeditions while still an undergraduate and published his first book (*Russian Waters*, 1931) before he completed his degree. He was a member of the party that discovered Prince Charles Island, the "last major island to be marked on the world's map." He held academic positions at McGill University, and at universities in Iraq and Nigeria, among others.

Perhaps unknown to general readers more familiar with his visible roles as editor, writer, and environmental activist, Polunin was a productive research biologist, specializing in arctic vegetation and plant ecology and, later, on marine ecosystems. His 1960 text on plant geography is one of the best known in that field and still in print over forty years later.

Myers remembered Polunin as a "scientist in the round," an appropriate epitaph for one whose legacy includes two influential international journals, ever renewed encouragement to scientists to focus more clearly on global issues of conservation and environmental science, a better informed and more aware public around the world, and more realistic hopes for a better quality of life for all humanity and for continued maintenance of the diversity of Earth's natural biota.

Polybrominated biphenyls

A mixture of compounds having from one to ten **bromine** atoms attached to a biphenyl ring, analogous to polychlorinated biphenyl (PCB)s. Manufactured as fire retardants, PBBs were banned after a 1973 Michigan incident when pure product was accidently mixed with cattle feed and distributed throughout the state. PBBs were identified as the cause of weight loss, decreased milk production, and **mortality** in many dairy herds. Approximately 30,000 cattle, 1.5 million chickens, 1,500 sheep, 6,000 hogs, 18,000 pounds (8,100 kg) of cheese, 34,000 pounds (15,300 kg) of dried milk products, 5 million eggs, and 2,700 pounds (1,215 kg) of butter were eventually destroyed at an estimated cost of $1 million. Although human exposures have been well-documented, long term epidemiological studies have not shown widespread health effects.

Polychlorinated biphenyls

Mixture of compounds having from one to ten **chlorine** atoms attached to a biphenyl ring structure. There are 209 possible structures theoretically; the manufacturing process results in approximately 120 different structures. PCBs resist biological and heat degradation and were used in numerous applications, including dielectric fluids in capacitors and transformers, heat transfer fluids, hydraulic fluids, plasticizers, dedusting agents, adhesives, dye carriers in carbonless copy paper, and **pesticide** extenders. The United States manufactured PCBs from 1929 until 1977, when they were banned due to adverse environmental effects and ubiquitous occurrence. They bioaccumulate in organisms and can cause skin disorders, liver dysfunction, reproductive disorders, and tumor formation. They are one of the most abundant organochlorine contaminants found throughout the world. *See also* Organochloride

Polycyclic aromatic hydrocarbons

Polycyclic aromatic **hydrocarbons** are a class of organic compounds having two or more fused **benzene** rings. While usually referring to compounds made of **carbon** and **hydrogen**, PAH also may include fused aromatic compounds containing **nitrogen**, sulfur, or cyclopentene rings. Some of the more common PAH include naphthalene (2 rings), anthracene (3 rings), phenanthrene (3 rings), pyrene (4 rings), chrysene (4 rings), fluoranthene (4 rings), benzo(a)-pyrene (5 rings), benzo(e)pyrene (5 rings), perylene (5 rings), benzo(g,h,i)perylene (6 rings), and coronene (7 rings).

PAH are formed by a variety of human activities including incomplete **combustion** of **fossil fuels**, wood, and **tobacco**; the **incineration** of **garbage**; **coal gasification** and liquefaction processes; smelting operations; and coke, asphalt, and **petroleum** cracking; they are also formed naturally during forest fires and volcanic eruptions. Low molecular-weight PAH (those with four or fewer rings) are generally vapors while heavier molecules condense on submicron, breathable particles. It is estimated that more than 800 tons of PAH are emitted annually in the United States. PAH are found worldwide and are present in elevated concentrations in urban aerosols, and in lake sediments in industrialized countries. They also are found in developing countries due to **coal** and wood heating, open burning, coke production, and vehicle exhaust.

The association of PAH with small particles gives them atmospheric residence times of days to weeks, and allows them to be transported long distances. They are removed from the **atmosphere** by gravitational settling and are washed out during precipitation to the earth's surface, where they accumulate in soils and surface waters. They also directly enter water in discharges, **runoff**, and **oil spills**. They associate with water particulates due to their low water solubility, and eventually accumulate in sediments. They do not bioaccumulate in biota to any appreciable extent, as they are largely metabolized.

Many but not all PAH have carcinogenic and mutagenic activity; the most notorious is benzo(a)pyrene, which has been shown to be a potent **carcinogen**. Coal tar and soot were implicated in the elevated skin **cancer** incidence found in the refining, shale oil, and coal tar industries in the late nineteenth century. Subsequent research led to the isolation and identification of several carcinogens in the early part of this century, including benzo(a)pyrene. More recent research into the carcinogenicity of PAH has revealed that there is significant additional biological activity in urban aerosols and soot beyond that explained by known carcinogens such as benzo(a)pyrene. While benzo(a)pyrene must be activated metabolically, these other components have direct biological activity as demonstrated by the **Ames test**. They are polar compounds, thought to be mixtures of mono- and dinitro-PAH and hydroxy-nitro derivatives. Tobacco smoking exposes more humans to PAH than any other source.

Polycyclic organic compounds

In organic chemistry, a cyclic compound is one whose molecules consist of three or more atoms joined in a closed ring. A polycyclic compound is one whose molecules contain two or more rings joined to each other. Environmentally, the most important polycyclic organic compounds are the **polycyclic aromatic hydrocarbons**, also known as polynuclear aromatic **hydrocarbons** (PAHs). Some examples of polycyclic organic compounds include naphthalene, anthracene, pyrene, and the benzopyrenes. A number of polycyclic hydrocarbons pose hazards to human health. For example, benzo(a)pyrene from **automobile** exhaust and **tobacco smoke** is known to be a **carcinogen**. *See also* Cigarette smoke

Polystyrene

Polystyrene is a lightweight transparent plastic derived from **petroleum** by-products and **natural gas**. It is widely used in the packaging industry, but most polystyrene is used to make durable goods such as television cabinets, appliances, and furniture. Polystyrene also has excellent insulating properties. As packaging, polystyrene is used both in foam and solid forms. Solid polystyrene is used in yogurt, sour cream, and cottage cheese containers, cutlery, clear clamshells used at salad bars, and video and audio cassette containers. As foam, polystyrene is used in cups, bowls, plates, trays, clamshell containers, meat trays, egg cartons, and packaging for electronics and other delicate items. Polystyrene foam is manufactured by processing solid polystyrene resin pellets with a gaseous expansion agent. In the past, about 30% of polystyrene foam products were made with **chlorofluorocarbons** (CFCs), which were identified as contributors to the deterioration of the **ozone** layer in the Earth's upper **atmosphere**. By 1990, manufacturers had phased out the use of CFCs as a polystyrene expansion agent. Some manufacturers switched to the use of hydrochlorofluorocarbon-22 (HCFC-22), which reduced **ozone layer depletion** potential by about 95% over CFCs. By 1994, as required by federal law, polystyrene foam manufacturers phased out the use of HCFC-22 and by 1997 were using alternative expansion agents, most commonly pentane gas. Pentane does not affect the ozone layer, but because it can contribute to **smog** formation some manufacturers recycle pentane emissions. **Carbon dioxide** (CO_2) is also used by manufacturers as a polystyrene expansion agent. CO_2 is nontoxic, nonflammable, does not contribute to smog, and has no atmospheric ozone depletion potential, but it has been implicated in global warming.

Polystyrene packaging accounts for about 1.2 % (by weight) of the total solid **waste stream** in the United States, and polystyrene makes up from about 2-10% of materials thrown away as litter. However, polystyrene can be recycled and used to make new polystyrene products such as wall insulation, packing filler, and cafeteria trays. Polystyrene has an energy content of 17,000 Btu/pound, about four times that of average **municipal solid waste**, and can be burned with other solid wastes in an incinerator that has appropriate **emission** controls to contain potentially toxic **combustion** products. Another potential environmental concern is the release of toxic metals such as **cadmium** and **lead** from combustion of inks used to tint the polystyrene. The polystyrene manufacturing industry is developing source reduction techniques, including improving resin properties to make stronger products with less material and making lighter-weight foam products.

Polystyrene is manufactured from **styrene**, which is a hazardous chemical. When styrene is heated to 392°F (198°C), it is converted into the polymer polystyrene. Health concerns have been raised about styrene residues remaining in polystyrene products, especially those that are used to contain food for consumption. Styrene is soluble in oil and in **ethanol**, substances commonly found in foods and alcoholic beverages. A U.S. EPA National Human Adipose Tissue Survey in 1986 identified styrene in 100% of the 46 human fat samples collected.

Polyvinyl chloride

Polyvinyl chloride, also known as PVC, is a plastic produced by the polymerization of **vinyl chloride**. It is used with plasticizers to make packaging films, boots, garden hose, etc. Without plasticizers, PVC is used to make pipe, siding, shingles, window frames, toys, and other items. An attractive aspect of PVC for industry is its ability to withstand **weathering** and its **resistance** to **chemicals** and solvents. However, this attractive aspect is the major environmental concern for PVC and many other **plastics**. The great bulk of such plastic (about 98%) is neither reused nor recycled but occupies ever dwindling **landfill** space.

Population biology

Population biology is the study of the factors determining the size and distribution of a population, as well as the ways in which populations change over time. The discipline of population biology dates back to the 1960s, when researchers merged aspects of population **ecology** with aspects of population genetics. It employs a traditional empirical approach

which consists of observation of the numbers of individuals in a population and the variation in those numbers over time and space, and the measurement of physical (abiotic) factors and the living (biotic) factors that may affect population numbers.

Given optimum conditions, the populations of most organisms grow at a constant rate of increase, doubling in size at regular intervals, which is known as **exponential growth**. Exponential **population growth** is explosive but it is usually opposed by factors that reduce numbers, such as disease, predation, or harsh climates. The result is **logistic growth**, where the rapidly growing population slows and reaches a stable but dynamic equilibrium at or near the **carrying capacity** of the **environment**. The populations of some **species** such as migratory locusts show boom and bust cycles: in these cases explosive growth produces vast numbers of individuals that eventually overwhelm the carrying capacity and a catastrophic **dieback** follows.

The rate of growth of a population is the net result of the gains and losses from a number of intrinsic factors operating within the population. These include natality, **fecundity**, life span, longevity, **mortality**, and immigration and emigration. Patterns of **survivorship** and age structure created by these interacting factors show how a population is growing and indicate what general role a species plays in the **ecosystem**. Density-dependent biotic factors that decrease natality or increase mortality include the numbers of competitors both interspecific and intraspecific, as well as predators, prey, **parasites**, and other interactive species. Stress and overcrowding are other density-dependent biotic factors that limit population size through excessive intraspecific **competition** for limited resources.

The local distribution pattern of populations of most species is limited by physical factors such as temperature, moisture, light, **pH**, **soil** quality, and **salinity**. Within their areas of distribution, animals occur in varying densities (either scattered thinly or crowded) and in varying dispersal patterns (either spaced evenly or clumped into herds). Population density and dispersion are often studied together, and are important in ecology and management. Density is measured by direct visual count, and by **trapping**, collecting fecal pellets, using pelt records, monitoring vocalization frequencies, and so on. Life tables constructed from these data show precisely how a population is age-structured.

Population genetics recognizes two important attributes of a population--its gene frequencies and its total **gene pool**. Population size exerts some influence on the genetic composition of its members, since the number of sexually interbreeding individuals influences the transfer of genes within a population. It also affects the kinds of genotypes that are available, and the survival and reproductive capacity of individuals with certain genes. The application of the principles of population genetics is vital to the success of programs to improve the breeds of animals and plants for agricultural use, and for the captive breeding of **endangered species**. *See also* Captive propogation and reintroduction; Gene bank; Genetic engineering; Predator-prey interactions; Sustainable development; Wildlife management

Population Council

The Population Council was established in 1952 to find solutions to the world's population problems. Although based in New York, the Council is an international nonprofit organization with regional offices in Bangkok, Cairo, Dakar, Mexico City, and Nairobi. In conducting research in health, social, and biomedical sciences, the Council has, among other accomplishments, broken ground in contraceptive devices, explored male fertility, and analyzed the social position of women and its concurrent effect on the population.

The Council seeks to use science and technology to provide relief to the population problems of developing countries. Governed by a board of 20 trustees from 16 countries who meet twice a year, the Council has programs in 50 countries throughout Latin America, the Caribbean, Asia, and Africa. It receives funding from world governments, United Nations agencies, foundations, and individuals for its research and programs. The major programs and institutions of the Population Council are the Center for Biomedical Research, the Research Division, and the Programs Division.

The Center for Biomedical Research investigates new ways to regulate human fertility, primarily through development of new methods of contraception. For example the

Center invented the Norplant levonorgestrel implant and a copper-bearing T-shaped intrauterine device (IUD). Both methods are for long-term protection and are reversible. Other methods include a hormone-releasing IUD, Norplant II (with two implants instead of six), and contraceptive vaginal rings. Another idea in progress includes a vaginal contraceptive that provides protection from the human immunodeficiency **virus** (HIV). These methods are designed for women, but the Center for Biomedical Research also concentrates on controlling male fertility through research into male physiology. With particular interest in creating a contraceptive to block sperm production without dampening the male sex drive, the Center is working on a "nonsurgical" or "no-scalpel" vasectomy and male subdermal implants, akin to women's Norplant.

The Population Council does not restrict its research to the biomedical domain, however. Through its Research Division, it looks for solutions to population problems through social research. A small interdisciplinary group of demographers, economists, sociologists, and anthropologists make up the Research Division. Among notable studies is an ongoing project examining the consequences of high fertility in a family. For instance, early research indicates that in Maharashtra, India, the advantages associated with growing up in a small family exist for boys but not for girls. Apparently in many smaller families in India, girls have a proportionately heavier burden of labor. The Research Division also conducts many studies in China, where the state is heavily involved in regulating its population. Through research into **family planning** and fertility, child survival, and women's roles and status—a subject that has taken precedence in the Council's research since 1976—the Research Division provides theories that the Population Council puts to use in controlling worldwide population problems.

The Council applies the research conducted by the Center for Biomedical Research and the Research Division through its Programs Division. The Programs Division collaborates with governments, organizations, and scientific institutions of developing countries to formulate population policy. Many of the programs set forth by this division parallel studies being conducted by the Research Division. For example, the Programs Division conducts family planning and fertility counseling; works to insure reproductive health and child survival; and seeks to improve women's roles and status in developing countries. The contraceptive introduction program is also an important part of the Programs Division.

In addition to its programs and research, the Council publishes two scholarly journals: *Population and Development Review* and *Studies in Family Planning*. Both contain studies of current ideas and theories in population control. The Population Council also sponsors outstanding scholars and scientists to further research into the technology needed to control the world's populations.

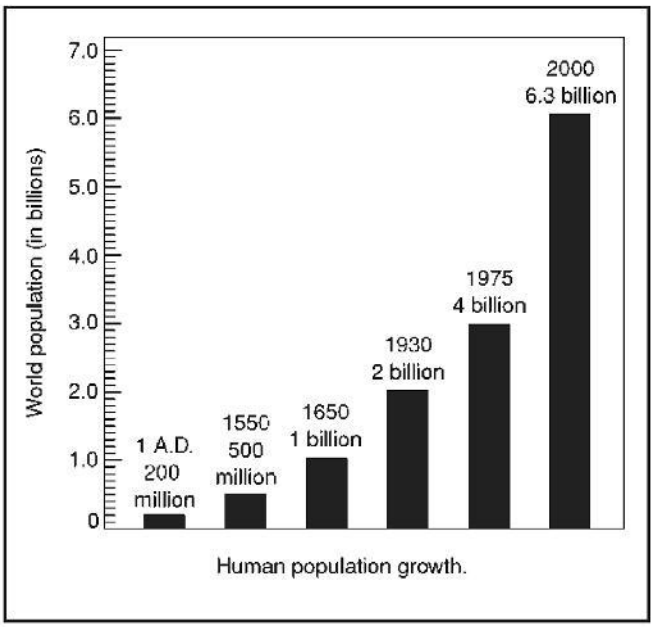
Population growth

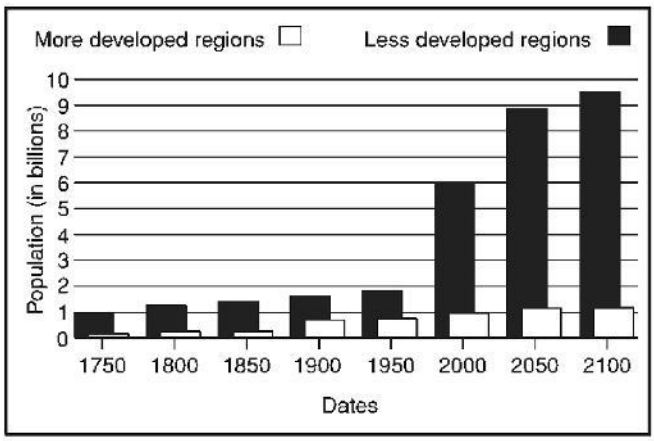
A population is the number of individuals of a given **species**, usually within a specified **habitat** or area. Within the science of **ecology**, the study of population dynamics, or the ways in which the number of individuals in a community expands and contracts, makes up an important subfield known as **population biology**. While ecologists and **wildlife** biologists rely on understanding the nature of population change and the factors that influence population size, one of the main ways population studies have been used is in projecting the growth of the human population. Since the 1960s human population growth has been an issue of fierce theoretical debate. Many scientists and social planners predict that the human population, like animal populations frequently observed in nature, is growing at a perilous rate that will ultimately lead to a catastrophic **die-off** in which billions of people will perish. Other scholars and planners argue that current trends may not lead to disaster and that we may yet find a reasonable and stable population level. Both sides of the debate use ecological principles of population biology in predicting human population dynamics and their effect upon the conditions in which we may live in the future.

The extent of population growth is based on fertility, or the number of offspring that individuals of reproductive age successfully produce. In some animal and plant species (flies, dandelions) every individual produces a great number of offspring. These populations grow quickly, as long as nutrients and space are available. Other species (**elephants**, pandas) produce few offspring per reproductive adult; populations of these species usually grow slowly even when ample food and habitat are available. The maximum number of offspring an organism can produce under ideal conditions is known as the biotic potential of that organism. For instance, if an individual housefly can produce 120 young in her lifetime, and each of those successfully produces 120 young, and so on, the fly's biotic potential in one year (seven generations) is nearly six trillion flies. Clearly biotic potentials are rarely met: reproductive failures and life hazards usually prevent the majority of houseflies, like other species, from achieving their theoretical reproductive potential.

Populations increase through reproduction, but they do not increase infinitely because of environmental limitations, including disease, predation, **competition** for space and nutrients, and **nutrient** shortages. These limits to population growth are collectively known as environmental **resistance**.



An important concept in environmental resistance is the idea of **carrying capacity**. Carrying capacity is the maximum number of individuals a habitat can support. In any finite system, there is a limited availability of food, water, nesting space, and other essentials, which limits that system's carrying capacity. When a population exceeds its environment's carrying capacity, shortages of nutrients or other necessities usually weaken individuals, reduce successful reproduction, and raise death rates from disease, until the population once again falls below its maximum size. A population that grows very quickly and exceeds its environment's carrying capacity is said to overshoot its environment's capacity. A catastrophic **dieback**, when the population plummets to well below its maximum, usually follows an overshoot. In many cases populations undergo repeated overshoot-dieback cycles. Sometimes these cycles gradually decrease in severity until a stable population, in equilibrium with carrying capacity, is reached. In other cases, overshoot-dieback cycles go on continually, as in the well known case of lemmings. Prolific breeding among these small arctic rodents leads to a population explosion every four to six years. In overshoot years, depletion of the vegetation on which they feed causes widespread undernourishment, which results in starvation, weakness, and vulnerability to predators and disease. The lemming population collapses, only to begin rebuilding, gradually approaching overshoot and another dieback. At the same time, related populations fluctuate in response to cycles in the lemming population: populations of owls and foxes surge when lemmings become plentiful and fall when lemmings are few. The grasses and forbs on which lemmings feed likewise prosper and diminish in response to the lemming population.



As a population grows, the number of breeding adults increases so that growth accelerates. Increase at a constant or accelerating rate of change is known as **exponential growth**. If each female lemming can produce four young females, and each of those produces another four, then the population is multiplied by four in each generation. After two generations there are 16 (or 24) lemmings; after three generations there are 64 (34); after four generations there are 256 (44) lemmings, if all survive. When environmental resistance (predation, nutrient limitations, and so on) causes a population to reach a stable level, without significant increases or decreases over time, population equilibrium is achieved. Generally we might consider stable (equilibrium) populations the more desirable situation because repeated diebacks involve extensive suffering and death.

These principles of population biology have strongly informed our understanding of human population changes. Over the centuries the world's human population has tended to expand to the maximum allowed by available food, water, and space. When humans exceeded their environment's carrying capacity, catastrophic diebacks (usually involving disease, **famine**, or war) sometimes resulted. However, in many cases, diebacks have been avoided through emigration, as in European migrations to the Americas, or through technological innovation, including such inventions as agriculture, **irrigation**, and mechanization, each of which effectively expanded environmental carrying capacities. For tens of thousands of years the human population climbed very gradually, until about the year 1000, when it began to grow exponentially. Where we once needed a thousand years (200 to 1200 A.D.) to double our population from 200 million to 400 million, at current rates of growth we would require only 40 years to double our population. Since the eighteenth century, population theorists have increasingly warned that our current pattern of growth is leading us toward a serious overshoot, perhaps one that will permanently damage our **environment** and result in a consequent dieback. The only course to avoid such a catastrophe, argue population theorists, is to stabilize our population somewhere below our environment's carrying capacity.

Popular awareness of population issues and agreement with the principle of population reduction have spread in recent years with the publication of such volumes as *The Population Bomb* by Paul Ehrlich, and *The Limits to Growth* by Donella Meadows and others. The current population debate, however has older roots, especially in the work of Thomas Malthus, an English cleric who in 1798 published *An Essay on the Principle of Population as It Affects the Future Improvement of Society*. Malthus argued that, while unchecked human population growth increases at an exponential rate, food supplies increase only arithmetically (a constant amount being added each year, instead of multiplying by a constant amount). The consequence of such a disparity in growth rates is starvation and death. The remedy is to reduce our reproductive rates, where possible by "moral restraint," but where necessary by force. Malthus' work has remained well-known principally because of its conclusion about social policy: because providing food and shelter to the poor only allows them to increase their rates of "breeding," assistance should be withheld. If the poorer classes should starve as a result, argued Malthus, at least greater rates of starvation at a later date would be avoided. This conclusion continues to be promoted today by neo-Malthusians, who protest the principle of aiding developing countries. Poorer countries, neo-Malthusians point out, have especially dangerous

A comparison of population growth in less developed and more developed regions, 1750-2100.

Contrasting the growth (exponential for less developed).

Human population growth. (Illustration by Electronic Illustrators Group.)

growth rates. If wealthy countries provide assistance today because they cannot bear to watch the suffering in poorer nations, they only make the situation worse. By giving aid, donor nations only postpone temporarily the greater suffering that will eventually result from artificially supported growth rates.

Naturally this conclusion is deeply offensive to developing nations and to those who sympathize with the plight of poorer countries. Malthusian conclusions are especially harsh in situations where military and economic repression, often supported by North American and European governments, have caused the poverty. Those who defend aid to developing countries argue that high reproductive rates often result from poverty, rather than vice versa. Where poor nutrition and health care make infant **mortality** rates high, parents choose to have many children, thus increasing the odds that at least some will survive to support them in their old age. Assistance to poor countries, and to poor areas within a single country, argue anti-Malthusians, helps to alleviate the poverty that necessitates high birth rates. When people become confident of their childrens' survival, then birth rates will drop and population equilibrium may be achieved.

There are some ways in which ecological principles of population dynamics do not necessarily fit the human population. Improving health care and increasing life expectancies have caused much of this century's population expansion. Wars, changes in prosperity, development and **transportation** of resources, and social changes sometimes increase or decrease populations locally. Immigration and emigration tend to redistribute populations from one region to another, temporarily alleviating or exacerbating population excesses. Also unlike most animals, we have not historically been subject to a fixed environmental carrying capacity. The **agricultural revolution**, the industrial revolution and other innovations have expanded our environment's capacity to support humans. Some population theorists today, known as technological optimists, insist that, even as the human population continues to grow, our technological inventiveness will help us to feed and shelter the world's population. Even in the past 50 years, when the world's population has jumped from less than three billion to more than six billion, world food production has exceeded population growth. Technological optimists point to such historical evidence as support for their position.

Also unlike most animal populations, humans are, at least in principle, able to voluntarily limit reproductive rates. Most population theorists point to some sort of voluntary restraint as the most humane method of preventing a disastrous population overshoot. **Family planning** programs have been developed around the world in an effort to encourage voluntary population limits. Furthermore, human societies have been observed to go through a **demographic transition** as their economic and social **stability** has improved. A demographic transition is a period when (infant) mortality rates have decreased but people have not yet adjusted their reproductive behavior to improved life expectancies. After 20 to 30 years, people adjust, realizing that more children are surviving and that smaller families now have economic advantages. The birth rate then begins to fall. While families in poor countries often have five to ten children, the average family in developed countries has about two children.

Because of family planning programs and demographic transitions, birth rates around the world have fallen dramatically in just the last 20 years. Where the average number of children per woman was 6.1 in 1970, the average number in 1990 was only 3.4. This rate still exceeds the minimum replacement level (**zero population growth** level) of 2.1 children per woman, but if recent demographic trends continue the world's population will stabilize within the first decade of the twenty-first century.

No one knows exactly what the earth's carrying capacity is. Some warn that we have already surpassed our safe population size. Others argue that the earth can comfortably support far more people than it currently does. Many worry about what would happen to other species if the human population continues to expand. Most people agree that we would benefit from a decrease in population growth rates. How urgent the population question is and how best to curb growth rates are issues that continue to be hotly debated.

Population Institute

Despite the fact they work with an annual budget of less than $2 million, the Population Institute, an information, education, and communication organization that spreads the word on population control, has been able to reach 172 countries, principally in the developing world. Based on the philosophy that overpopulation affects all social, economic, and political issues, the Institute's goal is to bring world population into balance with available environmental resources. To do this, the organization disseminates information via a World Population News Service which is picked up in developing countries in newspaper articles, editorial pieces, and radio and television broadcasts. In addition to making people aware of the perils of overpopulation, the Institute encourages birth control, without emphasizing any particular method.

Once a year the Institute funds an international journalism award, the Global Media Award in Population Reporting. The winner spends about one week touring a country with a successful population control program, visiting family planning clinics, and talking with government and private officials. Governmental leaders within the country usually present the award. The Institute benefits by keeping in contact not only with leaders and people at the grassroots level, but with local journalists.

Begun in 1969 by a Methodist minister with a strong conviction that overpopulation was a major cause of human misery, the Population Institute was one of the first groups organized specifically around population control. No longer connected to the Methodist church, the Institute is supported by grants from foundations, private individuals, and the sale of its bimonthly newsletter, *Popline*. In 1980 its domestic component split and formed the Center for Population Options, also headquartered in Washington, D.C.

If contraceptive use is a valid indicator, things are looking up for population control. Between 1970 and 2000, contraceptive use rose from 9–64%. If use can be increased to 72% within the next few years, World Bank statistics predict that world population can be stabilized at 8.5–11 billion.

Eliot Furness Porter (1901 – 1990)

American photographer

Born in Winnetka, Illinois, Eliot Porter's fascination with **nature** (and birds in particular) was evident from a very early age. His father, an architect with a keen interest in

Greek, Gothic, and Roman architecture and art, encouraged his son's insightful, artistic talents. Using the camera he received as a gift from his father, the young Porter began photographing primarily landscapes during the family's sojourns on islands off the coast of Maine. There he cultivated an enthusiasm and love for naturalist photography. He noted in the introduction of the classic book, *Birds of America*, "...the most satisfactory outlet for expressing my excitement over birds was the camera, rather than pencil or brush."

Porter began his undergraduate education at Harvard University in 1920. Casting aside his passion for photography, he pursued the more practical major of chemical engineering; he earned his bachelor's degree (cum laude) in 1924. He continued his education at Harvard's Medical School where he earned his doctor of medicine in 1929. Porter used his degrees to teach biochemistry and bacteriology at Harvard and Radcliffe College until 1939. In addition to his teaching, Porter was working through the Harvard Biology Department conducting numerous studies. By 1939, whatever attraction there had been to biochemistry diminished and Porter turned his energies back to photography. Determined to transform bird photography from less-than-professional reportage to art, Porter became involved with the Eastman Kodak company. Porter was awarded Guggenheim Fellowships in 1941 and again in 1946 to finance experiments with Kodachrome photography—a new venture for Kodak. He believed that by using the new color film, the photographer could provide a more sensitive interpretation of the subject.

Finally achieving success with color film, Porter produced a number of bird photography publications, including a photo-essay pairing his photos with specific Thoreau excerpts. The book, *In Wildness Is the Preservation of the World*, was published by the **Sierra Club**. Porter produced subsequent books with the organization (*Baja California—The Geography of Hope* and *The Place No One Knew: Glen Canyon on the Colorado*), and later—until 1971—served on the Sierra Club's Board of Directors.

While Porter's photography took him to locations throughout the world (Greece, Iceland, Turkey, and the Galapagos Islands), his most brilliant work came from his travels in eleven of the United States. *Birds of America—A Personal Selection* was the result of his trip and became one of his best-known books. It combines rich, full-color photographs with anecdotal notes detailing his trials and tribulations in taking them. Porter's other publications include *Galapagos—The Flow of Wilderness, Antarctica*, and *Intimate Landscapes*.

Porter's one-man exhibits have appeared in some of the most influential art institutes and museums in the United States, among them: the George Eastman House, Museum of Modern Art, Metropolitan Museum of Art, and Stieglitz's An American Place. He maintained membership in several organizations including Advocates for the Arts, American Civil Liberties Union, American Ornithologists' Union, and the Audubon Society.

Porter died in November 1990 in New Mexico following a heart attack; he had also suffered from Lou Gehrig's disease.

Positional goods

A concept coined by English economist Fred Hirsch (1931–1978) to describe goods or activities whose value depends on their exclusivity. For example, fame is considered a positional good since by definition only a few people can be famous and thus enjoy this "privilege." If everyone were famous, no one would be. Similarly, solitude on a mountain peak or in the **wilderness** would qualify as a positional good, since if one shared the peak or the wilderness with many other people, one could not experience solitude. Ironically, a positional good tends to diminish its own value because of the high demand it creates: as more people enjoy positional goods, they no longer become exclusive or valued. For instance, automobiles were once a positional good in America, but as more and more people began owning cars, they were no longer such a status symbol. A number of concerned environmentalists contend that access to wilderness areas should be restricted or limited to prevent the destruction of this positional good.

Posterity

Postmodernism and environmental ethics

Environmental ethics are a set of norms that a society accepts as a foundation for mediating and guiding their behavior towards the **environment**. In Western society, we have used our science, as well as other traditions (e.g. capitalist economics, humaneness, aesthetics), to form the foundation of our environmental behavior. We are in the midst of a search for new ethical foundations. **Deep ecology** has offered one possible route, Eastern religions have been another source for advancing our ethics, and yet none of these has proved palatable in our Western social systems.

Western science has guided the environmental interactions of our society which in turn has dominated global development processes, but this pattern has some definite shortcomings. While science has served to develop our understanding of **nature** and enhanced our knowledge of the ecological difficulties that we have created for ourselves, the system of which science is part has been very slow in responding to what many suggest is an ecological crisis. Sorting the science from the politics and the ethics of our society is not an easy task. Yet, science has been the target of criticism in the environmental arena because, while it has the power to expose the depth of our ecological crisis, it has done little in that regard. Critics point to that inaction as a negative structural attribute of how embedded science has become in our society.

An alternative proposed from within the humanist tradition in the social sciences suggests that science can only produce a false construction of nature. From this viewpoint science is tied to traditions that inevitably create an end product related to the position from which the observer views nature. Further it holds that all views of nature are constructed by humans who cannot step outside of ourselves to view the reality we think exists. Thus, no views are more or less closer to reality; they are all merely our creation. This alternative approach falls under the rubric of postmodernism and is elucidated through one of the principal methods in the postmodernist tool kit, deconstruction.

The deconstructionist approach of the postmodernist suggests that, even thought the views of all are equally worthy, an imbalance of power has been created by the dominant classes. The disempowered classes attempt to create a balance, a struggle which proceeds by dissecting everything down to its bare power relationships, so that having been revealed the wrong can be corrected. Deconstruction is a term that does not differ significantly from any other critical analytical method, but it pays particular homage to power and position, supposedly more conscientiously than other methods.

Nature "out there" then becomes a series of constructions made by humans with different positions within a continuum of power relations. Nature is the invention of humans in power and is constantly reinvented by people in those same positions. To the postmodernist, the present invention of nature, held by the current cadre of largely male, largely Caucasian scientists has given us a biased view of nature. The postmodernist wish is to level all points of view, so that life is seen as a struggle of words and nature becomes another, albeit large, "text" (a metatext). A rather curious outcome of this view of life is the idea that things in nature are doing what they do only because we think of them doing it. Furthermore, those who wish to protect nature may then become a force of oppression against those of other social orders who are struggling to gain power. Thus, a thinly disguised structuralist approach emerges. Power creates a framework within which the powerful struggle to remain empowered, and the remainder struggle to gain power. Environmental views supported by science are the handmaiden of the power elite and can only succeed in supporting the status quo.

While there is undoubtedly a cultural context in which nature is understood and in which science operates, this does not necessarily mean that context is equivalent to the content of nature. Even though reality may be seen as having been invented by words and the human shaping of sensory data, nevertheless there is much commonality across cultures regarding what we see in nature. The postmodernist view appears to be remote from the natural world, occupying an anthropocentric stronghold where humans are dominant. Interestingly, while humanists thus refer to a nature made by humans, scientists have since Darwin referred to humans as having been created by nature through natural selection.

The diametrically opposed view points under discussion here are not new; they merely reflect the range of opinions humans have always held about their relationship with nature. However, the postmodernist expression of human opinion about nature outlined above seems to be a position that is distinctly unhelpful, especially at this time in our existence. The heart of the environmental problems we currently experience has been blamed to a large degree on humanity's separation of itself from nature, and any proposal that maintains or widens that gap may exacerbate the problems. The postmodernist critique seems to ignore the power and influence that nature has on us, and instead uses an intricate semantics to describe the power we have over each other.

Most naturalists and ecologists are immediately struck by the apparent naiveté of a position that denies the creative strength in nature and the complex architecture of life provided by natural selection. A postmodern view is that our knowledge of distributions of organisms is a construct of

the way we have studied distributions, and the whole idea of **species** is merely a human distinction. The notion of objective criteria devised by, critiqued by, and used by scientists is rendered unusable. The postmodern view renders the concept that ecological tolerance of the organisms, historical events, and climate create a relationship based on a combination of determinist relationships and stochastic events a mere artifact regardless of how many people agree to the concepts. This of course leads to a conclusion which provides little guidance for environmental ethics.

That does not mean that the entire postmodernist critique leads to the same less than useful conclusions. Rather, the very aspect of a critique that causes us to examine our position may be an important and valuable tool. We have relied heavily on science and found at the center of **ecology** some powerful, yet largely incorrect, metaphors firmly rooted in our conception of nature. The ideas of balance, **succession**, and homogeneity in nature have all fallen by the wayside in the past two decades. Those readjustments have given ecologists pause because they are strong examples of how viewpoint can influence our interpretation of nature, one that was originally thought to have been discovered by an objective science. Are there more misconceptions that we hold about ecology and environment that need to be examined? Clearly the possibility exists, and it serves us well to search for those by any and all reasonable methods. That postmodernism creates the notion that all human perspectives are inherently equal may create an obstacle to clear thinking about proposing a comprehensive ethic towards the environment. At this time we need to synthesize a more positive relationship between nature and humanity to bring all of our cultures into an integrated understanding of nature. However, a revised ethical foundation for humanity's relationship with the environment may benefit from the tradition of critical thinking that various philosophical positions bring. An examination of biases linked to our present position.

John Wesley Powell (1834 – 1902)

American philosopher, geologist, anthropologist, and scientific explorer

John Wesley Powell—civil-war veteran, college professor, long-time head of the U.S. **Geological Survey**, member of the **National Academy of Sciences**, president of the American Association for the Advancement of Science, and instrumental in the establishment of the National Geographic Society, the Geological Society of America, the U.S. Geological Survey, the Bureau of Ethnology, and the Bureau of Reclamation—is best-known for two expeditions down the Green and Colorado Rivers.

Born in Mount Morris, New York, of English-born parents, Powell was discouraged from education by his father who believed that the ministry was the only purpose for which one needed to be educated. The younger Powell however, worked at a variety of jobs to support his attendance at numerous schools, but never completed a degree. His hard-won recognition as a scientist is based in large part on self-taught concepts and methods that he applied all his life and in everything he did.

Powell made significant contributions to **conservation** and **environmental science**. He was an early and ardent student of the culture of the fast-disappearing North American Indians tribes, and his work ultimately led to the creation of the Bureau of Ethnology, of which he was the first director. He served as the second Director of the United States Geological Survey (USGS) from 1881 to 1894, and as such he instigated extensive topographic mapping projects and geological studies, stimulated studies of soils, **groundwater**, and rivers, and advocated work on flood control and **irrigation**. His Irrigation Survey led eventually to the creation of first the **Reclamation** Service and then the **Bureau of Reclamation**.

Powell was the author of the *Report on the Lands of the Arid Region of the United States*, published in 1878. Through this document, he became an early advocate of land-use planning. Powell was open to controlled development and suggested that "to a great extent, the redemption of...these lands will require extensive and comprehensive plans..." In his role as director of the USGS, in his writings, his work on various commissions, and in public hearings, Powell advocated that the federal government assume a major role to insure an orderly and environmentally sound settlement of the **arid** lands of the West.

Wallace Stegner argues that Powell's ultimate importance derives from his impact as an agent of change, from setting in motion ideas and agencies that still benefit the country today. He also widens Powell's impact, asserting that Powell's ideas, through his friend and employee W. J. McGee, heavily influenced the whole conservation movement at the beginning of the twentieth century. Powell informed the American public of the grandeur and vulnerability of the arid lands and canyon lands of the West. The legacy of that heritage is the Grand Canyon still largely unspoiled as well as a better understanding of **land use** possibilities on arid and all lands.

Power lines

see **Electromagnetic field**

Power plants

The term power plant refers to any installation at which electrical energy is generated. Power plants can operate using any one of a number of fuels: oil, **coal**, nuclear material, or geothermal steam, for example. The general principle on which most power plants operate, however, is the same. In such a plant, a fuel such as coal or oil is burned. Heat from the burning fuel is used to boil water, converting it to steam. The hot steam is then used to operate a steam turbine.

A steam turbine is a very large machine whose core is a horizontal shaft of metal. Attached to the horizontal shaft are many fan-shaped blades. As hot steam is directed at the turbine, it strikes the blades and causes the horizontal shaft to rotate on its axis. The rotating shaft is, in turn, attached to the shaft of an electric generator. The pressure of hot steam on turbine blades, is therefore, ultimately converted into the generation of a electric current. One of the first steam turbines designed to be used for the generation of electricity was patented by Charles Parson in 1884. Twenty years later, entrepreneurs had already put such turbines to use for the generation of electricity for street lines, subways, train lines and individual appliances.

Most early power plants were fueled with coal. Coal was the best-know, most abundant fossil fuel at the time. It had several disadvantages, however. It was dirty to mine, transport, and work with. It also did not burn very cleanly. Areas around a coal-fired power plant were characterized by clouds of **smoke** belching from smokestacks and films of ash deposited on homes, cars, grass, and any other exposed surface.

By the 1920s interest in oil-fired power plants began to grow. The number of these plants remained relatively low, however, as long as coal was inexpensive. But, by the 1960s, there was a resurgence of interest in oil-fired plants, largely in response to increased awareness of the many harmful effects of coal **combustion** on the **environment**. One of the most troublesome effects of coal combustion is **acid rain**. Coal contains trace amounts of elements which produce acid-forming oxides when burned. The two most important of these elements are sulfur and **nitrogen**. During the combustion of coal, sulfur is oxidized to **sulfur dioxide** and nitrogen to nitric oxide. Both sulfur dioxide and nitrogen oxide undergo further changes in the **atmosphere**, forming sulfur trioxide and nitrogen dioxide. Finally, these two oxides combine with water in the atmosphere to produce sulfuric and nitric acids.

This series of chemical reactions in the atmosphere may take place over hundreds or thousands of miles. Oxides of sulfur and nitrogen that leave a power plant smokestack are then carried eastward by prevailing winds. It may be many days or weeks before these oxides are carried back to earth—now as acids—in rain, snow, or some other form of precipitation. During the 1960s and 1970s, many authorities became concerned about the possible effects of **acid** precipitation on the environment. They argued that the problem could be solved only at the source—the electric power-generating plant.

One approach to the reduction of pollutants from a power plant is the installation of equipment that will remove undesirable materials from waste gases. An electrostatic precipitator is one such device which removes particulates. It

attaches electrical charges to the particulates in waste gases and then applies an opposing electric field to a plate that attracts the particulates and removes them from the waste gas stream. **Scrubbers**, **filters**, and **cyclone** collectors also remove harmful pollutants from waste gases.

Another approach to acid rain and other power-plant-generated **pollution** problems is to switch fuel from coal to oil or **natural gas**. Although **petroleum** and natural gas also contain sulfur and nitrogen, the concentration of these elements is much less than it is in many forms of coal. As a result, a number of electrical utilities began to retrofit their generating plants in the 1960s and early 1970s to allow them to burn oil or natural gas rather than coal. This change-over is reflected in the increased use of petroleum by electrical utilities in the United States between 1965 and 1975. Consumption increased more than six-fold in that ten year period, from about 100 million barrels per year to more than 6,700 million barrels per year. Interestingly enough, the use of coal by utilities did not drop off during the same period, but continued to rise from about 200 million short tons to over 300 million short tons annually.

This pattern of **fuel switching** turned out to be short-lived, however. Although oil and natural gas are relatively clean fuels, they also appealed to utilities because of their relatively low cost. The **oil embargo** instituted by the **Organization of Petroleum Exporting Countries** (OPEC) in 1973 altered that part of the equation. Worldwide oil prices jumped from $1.36 per million **Btu** in 1973 to $2.23 per million Btu in 1975, an increase of 64 percent per million Btu in just two years. A decade later, the price of oil had more than doubled. And, the situation was even worse for natural gas. The cost of a million Btu of this resource skyrocketed from 36.7 cents in 1970 to 69.3 cents in 1975 to $2.23 in the mid-1980s.

Suddenly, the conversion of power plants from coal to oil and natural gas no longer seemed like such a wonderful idea. And the utilities industry began once more to focus on the fossil fuel in most plentiful supply—coal. Between 1975 and 1990, the fraction of power plants powered by oil and natural gas dropped from 12% to 4% for the former and from 24% to less than 10% for the latter. In the same period, the fraction of plants powered by coal rose from 46%–57%.

Power plants using **fossil fuels**, of whatever kind, are not the world's final solution to the generation of electricity. In addition to the environmental problems they cause, there is a more fundamental limitation. The fossil fuels are a nonrenewable resource. The time will come—sooner or later—when coal, oil, and natural gas supplies will be depleted. Thus, research on alternatives to fossil-fuel-fired plants has gone on for many decades.

Thirty years ago, many people believed that **nuclear power** was the best solution to the world's need to produce large amounts of electricity. Indeed, the number of nuclear power plants in the United States grew from 6 in 1965 to 95 in 1985. By 1992, 421 nuclear plants were in commercial operation worldwide, supplying 17% of the world's electricity. But enthusiasm for nuclear power plants began to wane in the 1980s. One reason for this trend was the serious accidents at the **Three Mile Island Nuclear Reactor** (Middletown, Pennsylvania) in 1979 and at the **Chernobyl Nuclear Power Station** (Chernobyl, Ukraine) in 1986. Another reason was the growing concern about disposal of the ever-increasing volume of dangerous radioactive wastes produced by a nuclear power plant. In any case, no new nuclear power plant has been ordered in the United States since the Three Mile Island accident and 65 plant orders have been canceled since that event. Forty-nine nuclear plants are now under construction in other parts of the world, but this number is only a quarter as many as were under construction a decade ago. Indeed, between 1990 and 1991, the total installed nuclear generating capacity worldwide declined for the first time since commercial nuclear power generation began. Given current economic and political conditions, a major revival of the nuclear power industry seems unlikely.

A nuclear power plant operates on much the same principle as does a fossil-fuel power plant. In a nuclear power plant, water is heated not by the combustion of a fuel like coal or oil, but by **nuclear fission** reactions that take place within the reactor core. Some scientists anticipate that another type of nuclear power plant—the fusion reactor—may provide a long-term answer to the world's electrical power needs. In a fusion reactor, atoms of light elements are fused together to make heavier elements, releasing large amounts of energy in the process. **Nuclear fusion** is the process by which stars make their energy and is also the energy source in the **hydrogen** bomb. Research efforts to develop an economic and safe method of controlling fusion power have been underway for nearly 40 years. Although progress has been made, a full-scale commercial fusion power plant currently appears to be many decade in the future.

Other types of power plants also have been under investigation for many years. For example, it is possible to operate a steam turbine with hot gases that come directly from geothermal vents. In locations where geysers or other types of vents exist, geothermal power plants are an economical, safe and dependable alternative to fossil-fueled and nuclear power plants. In the early 1990s, for example Pacific Gas and Electric in northern California obtained about eight percent of its electrical power from geothermal plants.

Finally, power plants that do not use heat at all are possible. One of the oldest forms of power plant is, in fact, the hydroelectric power plant. In a hydroelectric power plant,

the movement of water (as from a river) is directed again turbine blades, causing them to rotate. In 1970, 16 percent of all electric power in the United States came from hydropower although that portion has now fallen to less than eight percent.

Proposals for wind power generated-electricity, **tidal power** plants, and other alterative energy sources as substitutes for fossil fuels and nuclear power have been around for decades. During the 1960s and 1970s, governments aggressively encouraged research on these new technologies, offering both direct grants and tax breaks. Since 1980, however, the United States government has lost interest in alternative methods of power generation, preferring instead to encourage the growth and development of more traditional fuels, such as coal, oil and petroleum. *See also* Geothermal energy; Ocean thermal energy conversion; Solar energy; Tidal power; Wind energy

Prairie

An extensive temperate grassland with flat or rolling terrain and moderate to low precipitation. The term is most often applied to North American **grasslands**, which once extended from Alberta to Texas and from Illinois to Colorado, but similar grasslands exist around the world. Perennial bunchgrasses and forbes dominate prairie **flora**. In dry **climate** prairies, a lack of precipitation prohibits tree growth except in isolated patches, such as along stream banks. In wetter prairies, periodic fires are essential in preventing the incursion of trees and preserving open grasslands. Historically, huge herds of large mammals and scores of bird, rodent, and insect **species** composed native prairie **fauna**. During the nineteenth and twentieth centuries most of North America's native prairie **habitat** and its occupants disappeared in the face of agricultural settlement, cattle grazing, and fire suppression. Today the geographic extent of native prairie plants and animals is severely restricted, but pockets of remaining prairie are sometimes preserved for their ecological interest and genetic diversity.

A prairie. (Photograph by Robert J. Huffman. Field Mark Publications. Reproduced by permission.)

While grasses make up the dominant vegetation type in all prairies, grass sizes and species vary from shortgrass prairies, usually less than 20 inches (50 cm) high, to tallgrass prairies, whose grasses can exceed 7 ft (2 m) in height. Following the gradual east-west decrease in precipitation rates on the Great Plains, eastern tallgrass prairies gradually gave way to midgrass and then shortgrass prairies in western states. On their margins, prairie grasslands extended into a mixed "parkland," or "savanna," with bushes and scattered

trees such as oak and juniper. Characteristic prairie grasses are perennial bunchgrasses, which have deep, extensive root systems and up to a hundred shoots from a single plant. Bunchgrasses typically grow, sprout, and flower early in the summer when rainfall is plentiful in the prairies, and their deep root systems make the long-lived plants resistant to **drought**, hail, grazing, and fire. In addition to the dominant grasses, vast numbers of flowering annual and perennial forbes—herbaceous flowering plants that are not grasses—add color to prairie landscapes.

Prairie plant species are well adapted to live with fire. Under natural conditions fires sweep across prairies every few years. Prairie fires burn intensely and quickly, fed by dry grass and prairie winds, but they burn mainly the dry stalks of previous years' growth. Below the fire's heat, the roots of prairie plants remain unharmed, and new stalks grow quickly, fertilized by ashes and unencumbered by accumulations of old litter. Before European settlement, many prairie fires were ignited by lightening, but some were started by Indians, who had an interest in maintaining good grazing land for **bison**, antelope, and other game animals.

Well into the nineteenth century, prairie habitats supported a tremendous variety of animal species. Vast herds of bison, pronghorn antelope, deer, and elk ranged the grasslands; smaller mammals from mice and **prairie dogs** to badgers and fox lived in or below the prairie grasses. Carnivores including grey **wolves**, coyotes, cougar, grizzlies, hawks, and owls fed on large and small herbivores. Shorebirds and migratory waterfowl thrived on millions of prairie pothole ponds and marshes. Most of these species saw their habitats severely diminished with the expansion of agricultural settlement and cattle grazing range. Prairie soils, mainly mollisols, are rich and black with a thick, fertile organic layer composed of fine roots, **microorganisms**, and **soil**. Where water was available, this soil proved ideal for growing corn, wheat, soybeans, and other annual crops. Where water was scarce, nutritious bunchgrasses provided excellent grazing for cattle, which quickly replaced buffalo, elk, and antelope on the prairies in the middle of the nineteenth century.

Prairie habitat and animal species have also lost ground through fire suppression and wetland **drainage**. Farmers and ranchers have actively suppressed fires, allowing trees, exotic annuals, and other non-prairie species to become established. Widespread **wetlands** drainage has seriously diminished bird populations because of habitat loss. Especially in wetter northern and eastern regions, canals were cut into prairie wetlands, draining them to make arable fields. This practice continues today, even though it destroys scarce breeding grounds for many birds and essential migratory stopovers for others.

In recent decades increased attention has been given to preserving the few remaining patches of native prairie in North America. Public and private organizations now study and protect prairie grasslands and wetlands, but the long-term value of these efforts may be questionable because most remnant patches are small and widely separated. Whether genetic diversity can be maintained, and whether habitat for large or ranging animals can be reestablished under these conditions, is yet to be seen.

Prairie dogs

Prairie dogs, members of the genus *Cynomys*, belong to the squirrel family of the order *Rodentia*. There are five **species** of prairie dogs found on North American plains and plateaus from southern Saskatchewan, Canada to northern Mexico: Utah (*C. parridens*), Gunnison's (*C. gunnisoni*), white-tailed (*C. leucurus*), black-tailed (*C. ludovicianus*), and Mexican (*C. mexicanus*).

The explorer Meriwether Lewis, explorer of the American West, described prairie dogs as barking squirrels, which "bark at you as you approach them, their note being much like that of little toy dogs." These barking calls, including barks, chirps, and whistles, are used to communicate greetings, social status, and approaching or retreating danger.

Prairie dogs as social animals live in colonies, or "towns," which consist of extensive and complex underground burrows one to five meters deep. Cone-shaped mounds at the entrance of the burrows are used as look-out points; they also prevent water from entering the burrows. The burrows contain several chambers, including one near the entrance where the prairie dogs can listen for above-ground activity, as well as one or more nesting chambers where young prairie dogs sleep and are cared for. Prairie dogs generally prefer to eat grasses and herbs. They also clip vegetation in the vicinity of their colonies to provide clear views of predators. They spend daylight hours above-ground, grooming each other, grazing on grass, tumbling in play, and defending their family territorial boundaries.

A prairie dog. (U.S. Fish and Wildlife Service. Reproduced by permission.)

More than 200 other **wildlife** species are associated with prairie dog colonies, resulting in the increased biological diversity seen in prairie lands with colonies. Some of these animals are prairie dog predators, such as hawks, eagles, snakes, and coyotes, while others use the colonies as their **habitat**. The reduction and/or spread of certain insects and plants is also dependent on prairie dogs.

However, prairie dog populations have been greatly reduced, in some cases to one to two percent of their historical numbers. This decrease in prairie dog populations was, and continues to be, due to **poisoning**, **hunting**, and extermination campaigns by some ranchers who believe that prairie dogs compete for livestock forage. Long-term **overgrazing** by livestock has resulted in loss of grasses that prairie dogs depend on, as well as in **erosion** and destruction of prairie dog habitat. Additional habitat losses are due to development of lands for human housing and other uses. Prairie dogs are also susceptible to diseases, including the **plague**, which can wipe out entire colonies.

The **IUCN—The World Conservation Union** lists the black-tailed and Utah prairie dogs at low risk and the Mexican prairie dog is already endangered. Environmental and citizen's groups are beginning to act to preserve prairie dog habitats throughout the western grassland areas that serve as their home lands.

Precision

Precision refers to the ability to repeat the same measurement and arrive at the same value. In **statistics**, precision refers to the difference between repeated measurements of the same quantity, where the closer the measurements are to each other; the greater the precision of the estimate of the quantity. Precise measurements are not necessarily accurate measurements, because the repeated measurements can be very close to the same value and still be far from correct. As an example, if the differences in ten measurements of the same distance are very close to each other, the distance-measuring device is considered to be precise. However, there is no surety that the distance measured is correct unless the device is also accurate.

[*Marie H. Bundy*]

Precycling

Precycling is source reduction and **reuse**. In most **waste management** planning the hierarchy is Reduce, Reuse, and Recycle. Reduction and reuse are the first lines of defense against increasing waste volume. Precycling are those actions that can be taken before **recycling** becomes an option. It is the decision on the part of a consumer to not purchase an unnecessary product or the decision to purchase a reusable as opposed to a disposable item. Precycling is using the china plates in the cupboard for a party instead of purchasing paper or plastic plates. It is also the decision to buy in bulk or to buy refillable containers and then purchasing the product in a bulk container that can refill a dispenser. Precycling is thinking ahead to the ultimate destination of the containers and packaging of products are bought and making the decision to reduce those that might end up in a **landfill**. In addition to individual decisions to reduce waste before it

happens there is the decision on the part of industry to reuse **chemicals** and to buy from parts suppliers that take back packaging and reuse it. Precycling is stopping waste before it happens. *See also* Green packaging; Green products; Solid waste

Predator control

Predator control is a **wildlife management** policy specifically aimed at reducing populations of predatory **species** either to protect livestock or boost populations of game animals. Coyotes, bobcats, grey and red **wolves**, bears, and mountain lions have been the most frequent targets. Historically, efforts were centered in government-run programs to hunt, trap, or poison predators, while bounties offered for particular predatory species encouraged private citizens to do the same. Over time, however, it has become apparent that predator control is disruptive of ecosystems and often inefficient.

Predator control is based on a lack of understanding of the complex interactive mechanisms by which natural environments sustain themselves. Control efforts take the position that prey populations benefit when predators are removed. In the long term, however, removing predators is generally bad for the prey species and their ecosystems. The conservationist **Aldo Leopold**, noticing the devastating effects of **overgrazing** by deer, realized as early as the 1920s that shooting wolves, although it led to an immediate increase in the deer population, ultimately posed a threat to the deer themselves as well as other **fauna** and **flora** in their **environment**. Another example can be found in the undesirable consequences of killing significant numbers of coyotes. Immediate benefits rebound not only to livestock but also to populations of rabbits and other rodents, which are normally controlled by predation. Since rabbits compete with livestock for the same rangeland, an explosion in the rabbit population simply means that the land can sustain fewer livestock animals.

In 1940, the **U.S. Department of the Interior** initiated a large-scale program against livestock predators, particularly aiming at the **coyote** and relying heavily on poisons. The poison most widely used in bait was sodium fluoroacetate, also called "compound 1080," which is highly persistent and wreaks havoc on many animals besides the coyote, including threatened and **endangered species**. Moreover, when a poisoned coyote dies, the carrion enters the **food chain/web**, with lethal effects primarily on scavengers. Eagles, including the rare **bald eagle**, are particularly hard-hit by efforts to poison coyotes.

Rising environmental awareness has caused continuing controversy over predator control. By 1972, the government-appointed Committee on Predator Control concluded that the use of poisons had unacceptably harmful consequences. Government agencies discontinued the use of poisons, and poison was banned on public lands. Nevertheless, private citizens, mostly ranchers and hunters who feel that their interests have been sorely overlooked, have continued using poisons with little regard for the law. In the 1980s the government started taking a less progressive stance, and in 1985 the Reagan administration reinstituted the use of compound 1080 in "livestock collars." While nonpredatory species will not fall victim immediately, the poison still enters the food chain with every coyote killed.

In spite of aggressive methods, the fight against coyotes has mostly been unsuccessful. Even after decades of predator control, total annual losses are given in the hundreds of thousands of animals (mostly sheep and goats) by ranchers who claim they lose as much as 25 percent of their lambs to predators each year. Conservationists and supporters of **wildlife** say these numbers are inflated, but, even if they are accurate, the cost of lost livestock is significantly lower than the cost of the government's predator control programs. **Conservation** groups argue that it would be much cheaper to give up on predator control and reimburse ranchers for livestock lost to predation.

Besides killing predators, ranchers also have a number of other options when it comes to protecting their livestock. Sheep can be protected by letting it graze together with cattle or other animals too big for coyotes to handle. Llamas and donkeys have also been suggested for the purpose. Trained guard dogs are an effective deterrent to coyotes as well.

Although predator control can clearly have devastating consequences, it is by no means a thing of the past. Recently, Alaska began implementing a program to shoot 1000 wolves (out of a total population of 7000 wolves in the state). The program, which is to remove the wolves from a vast, centrally located stretch of **wilderness** over a period of five years, will have government agents tracking and shooting packs of wolves from the air. Private citizens are also allowed to shoot wolves. The object is to boost moose and caribou herds for **hunting** and tourist purposes. The view that the value of animal resources lies primarily in their usefulness to human beings still motivates many government policies and individual behaviors.

Predator-prey interactions

The relationship between predators and their prey within an **ecosystem** is often a quite complex array of offenses and defenses. Predation is the consumption of one living organism by another. Predators must have ways of finding, catching, and eating their prey (the offensive strategies), and prey organisms must have ways of avoiding or discouraging this activity (the defensive strategies). Predator-prey interactions are often simply thought of as one animal, a carnivore, catching and eating another animal, another carnivore or an herbivore. The interrelationships of predators and their prey is much more involved than this and encompasses all levels within an ecological **food chain/web**, from plant-herbivore systems to herbivore-carnivore systems to three-way interactions of interdependent plant-herbivore-carnivore systems.

Even though a plant may not be killed outright, removing leaves, stems, roots, bark, or the sap from plants will reduce its fitness and ultimately its ability to survive. The younger, more tender leaves and stems of a plant are typically consumed by herbivores. Because these are sites of active growth, the plants send stores of nutrients from roots and other tissues to these developing regions. When they are eaten the plant is losing a disproportionate amount of nutrients that will be difficult to replenish. Severe **defoliation** results in a tremendous loss of vigor and the loss of the ability to photosynthesize and store energy reserves for the dormant season. Without this energy store available, the plants are more vulnerable to insect or disease attack the following year.

Plants have responded to herbivory in a variety of ways. Some plants have developed spines or thorns, whereas others have developed the ability to produce chemical products which deter herbivory by making the plant unpalatable, barely digestible, or toxic. Many herbivores have found ways to circumvent these defenses, however. Some insects are able to absorb or metabolically detoxify these **chemicals** from the plants. Other insects have learned to cut trenches in the leaves of plants before they eat them, which stops the flow of these chemical substances to the leaves. Other animals have developed digestive modifications, such as bacterial communities that break down cellulose, to enable them to ingest less nutritious, but more abundant, vegetation.

A classic example of predator-prey interactions in carnivores is the relationship of the lynx, snowshoe hare, and woody browse of northern coniferous forests. The hare feeds on buds and twigs of conifer, aspen, alder, and willow trees. Excessive browsing, as the hare population increases, decreases the subsequent year's growth, initiating a decline in the hare population. The lynx population follows that of the snowshoe hare, having greater reproductive success when more prey are available, then declining as hare populations drop. This relationship is cyclical and follows its course over a ten-year period.

The prey of carnivores, both herbivores and other carnivores, have developed a variety of defensive mechanisms to avoid being detected, caught, or eaten. Some employ chemicals, such as odorous secretions, stored toxic substances ingested from plants, or synthesized venom or poisons. Other animals have taken to hiding from predators through cryptic coloration, patterns, shapes, and postures. Mimicry, widespread in the animal kingdom, is a system whereby one animal, a palatable **species**, mimics an inedible species, and is thus avoided by the predator. Additional means of predator avoidance or discouragement involves the employment of armor coats or shells, the use of quills or spines, or living in groups. However, predators can benefit prey populations by removing sick or inferior individuals. Subtle, long-term interactions, in fact, can benefit both predator and prey as they co-evolve together into more highly adapted or finely-tuned forms. *See also* Evolution; Population biology

Prescribed burning

Intentional burning, usually in forests, prairies, and savannas, in order to maintain desired ecological conditions or prevent major wildfires that could result from accumulated dry, woody debris. Prescribed burning, also called controlled burning, has become a widely recognized component of modern **ecosystem management** in recent decades as ecologists and managers have recognized the role of fire in natural ecosystems. In practice, though, prescribed burning is still used only on a small portion of public and private lands. In a forest, prescribed burning is usually aimed at removing accumulated fuel—fallen branches, pine needles, and other

dry debris. In a **prairie** or **savanna environment**, prescribed burns may be used to prevent encroachment of trees, to reduce populations of nonnative grassland **species**, and to enhance the health of native grassland vegetation that is adapted to periodic fires.

The principle of prescribed burning is that fire is a normal component of ecosystems, and that frequent small fires can serve both to maintain species diversity and to prevent large, catastrophic wildfires. Under natural conditions wildfires, usually ignited by lightning, occur frequently in many forest and grassland biomes. Proponents of prescribed burning argue that these natural fires would usually be small and cool, occurring too frequently to allow excessive accumulation of fallen branches, dead grass, and other fuel. Frequent, low-intensity fires should do little damage either to mature trees or to the root systems of most plants. At the same time, by clearing away debris every few years, and by a natural fire regime should provide fresh ground, exposed to sunlight and freshly fertilized by ashes, to encourage new germination and plant growth.

Deliberate burning is also an age-old method of maintaining grazing lands in many parts of the world. Periodic forest burning to maintain pasturage and to clear farm plots has probably been practiced for millennia in Africa and South America. In North America, **indigenous peoples** used fire to maintain open forests and prairies that provide grazing for game animals such as deer and **bison**. In some areas, especially New England and the rural South, early European immigrants to the New World adopted Indian methods of burning. These practices differ from what is usually considered a prescribed burn, however, because they are often carried out without the planning and the careful fire control usually exercised in a controlled or prescribed burn. In most of North America, traditional burning practices have also disappeared as more and more forests have come under professional management for timber production.

The introduction of prescribed burning to professional land management strategies in the United States is often attributed to **Aldo Leopold**, who pointed out in 1924, while he was serving as a forester and firefighter in Arizona, that fire control programs were producing brush-choked forests susceptible to extreme **wildfire**. Leopold argued that decades of fire suppression had actually increased the **probability** of severe fires, and that forests were healthier when subject to regular, natural fires. Since Leopold began arguing for prescribed burning in the 1920s, **ecosystem** managers have widely recognized the ecological benefits of fire. The amount of prescribed burning carried out still remains modest, however. Between 1983–1994, prescribed burns were carried out on only about 0.1% of public lands in the United States each year, as compared to 0.3% burned annually by wildfires in the same interval.

Proponents of prescribed burning sometimes argue fire suppression techniques--bulldozed fire breaks, tree felling, air drops of chemical fire retardants, and other measures--cause more damage than the fires they are meant to control. In addition, these expensive, and dangerous, tactics may ultimately have little effect. Prescribed burn proponents argue that most large natural fires die out as a result of rainfall, cooler weather, or a lack of fuel, not because of the efforts of fire fighters. These opponents of standard military-style fire suppression programs propose that it would be more effective to use fire control budgets for planned burns than for impressive but useless shows of force against large forest fires. However events such as the **Yellowstone National Park** fires of 1988, a series of highly publicized fires that led to loud criticism from the media and politicians that Park officials were negligent in their duties to protect the park, demonstrate that the public is unlikely to settle for inactivity during a forest fire. During fires such as those in Yellowstone, the public is quick to criticize officials for doing nothing even if there is nothing to be done. Most of us would rather see a campaign to fight fires even if wastes money and causes serious damage to the forest.

Benefits of Prescribed Fires

Fire has many ecological benefits. By clearing patches of forest, fire allows tree seeds to germinate. The seedlings of many trees, including Douglas fir (*Pseudotsuga menziesii*) and white pine (*Pinus strobus*), both prized for timber, require the strong sunlight of an open patch in the forest to begin growing. Other species, such as jack pine (*Pinus banksiana*) require intense heat, such as that produced by a fire or extremely hot sun, to release the seeds from their resin-sealed cones. These trees are considered fire-adapted, because they reproduce best, or only, when seedlings can grow in the full sun and fresh ashes of recently burned patches of forest. Many prairie grasses and flowers are also fire adapted, thriving best when periodic fires remove dead stem litter and release stored nutrients to the **soil**.

Fire plays an important role in cleaning out damaged or diseased regions of a forest. Where **parasites**, fungus, or disease have damaged stands of trees, a fire can locally eliminate the **pest** population, reducing the risk of parasite or disease spread, at the same time as it removes standing dead trees and makes room for new seedlings to replace the damaged trees. Land managers in southern Alaska, faced with the worst spruce beetle outbreak ever in the United States, have recently begun to consider using prescribed fire to control beetles.

Undesirable species encroaching on **grasslands** and savannas can also be controlled with fire. Opportunistic trees and brush such as aspen, buckthorn, juniper and sumac, introduced European grasses, as well as nuisance species such as poison oak and poison ivy can all be set back by

periodic burning. At the same time, prescribed burns can rejuvenate fire-adapted plant populations by clearing debris and releasing nutrients to the soil. In a burned area increased sunlight can extend the growing season, an important advantage in cold climates. In addition, periodic patchy burns help maintain **habitat** diversity by producing a mosaic of landscape types and different-aged tree stands. Because many animal species utilize a variety of environments for feeding and nesting, a mosaic landscape maintained by fire can benefit **wildlife** populations.

Methods

A prescribed burn is a fire set under conditions that should allow control of the fire. Usually this means identifying the limits of an area that should be burned and creating or identifying fire breaks that will prevent the uncontrolled spread of the fire once it has been lit. Often a backfire is used. A backfire is line of fire burned on the downwind edge of the area to be burned. The backfire is kept low and forced to burn upwind until it has created a swath of land clear of any combustible fuel. Flank fires, similarly, clear combustible materials from strips along the flanks of the burn area. The main fire, moving forward in a downwind direction, will die out due to a lack of fuel when it reaches the blacked zone created by the backfire. In addition to these precautions, prescribed burning usually requires selecting a day with high humidity and light winds, to keep the fire relatively low.

Ideally areas should be burned periodically in order to mimic the pattern of natural fires. Fire ecologists and managers usually attempt to burn areas with the frequency they estimate would occur in local ecosystems under natural conditions. In some areas natural fire frequency might be as often as every 2-3 years; elsewhere natural fires might normally occur as infrequently as every 10-20 years. Or managers may simply burn any areas in which debris has accumulated to dangerous levels.

Prescribed Natural Fires

Sometimes a prescribed burn policy means establishing a rule to let naturally ignited fires, usually started by lightning, burn themselves out. When rules establish that fires should be allowed to burn, fires that occur are referred to as prescribed natural fires. "Let-burn" policies are widely applied in national parks and forests in the United States. Seventy-five percent of **Yosemite National Park**, for example, is treated as a prescribed natural fire zone. In large part this is because it is more politically palatable to allow **nature** to take its course than it is to deliberately burn a park. In addition, it is less costly to let fires burn naturally than to maintain a burn crew, design burn plans and fire breaks, and carry out and monitor a regular program of prescribed burns. Usually a prescribed natural fire policy sets limits on the conditions and size of fires that will be allowed to burn, and any natural fires that do occur are closely monitored to ensure that they do not become too large or dangerous.

History of Prescribed Burning in the United States

Two factors influenced the development of prescribed burning in the United States. One was the observation that despite decades of fire suppression, the number and intensity of wildfires has actually increased since the advent of major fire suppression programs. One United States **Forest Service** study showed that total acreage burned, after declining from 1917 to 1955, increased steadily from the 1960s to the 1990s. The other factor was a transition in ecological theory toward understanding ecosystems as complex and dynamic, not static structures that should be maintained a single, undisturbed, optimal climax state. The shift in ecological theory developed partly from the observation that ecosystems maintained rigorously by managers were not necessarily healthier, than those that underwent periodic catastrophic events such as floods and fires. In fact, according to this theory, ecosystems may require periodic change and disruption in order to remain healthy.

The Nature Conservancy, which maintains scattered patches of native prairie, savanna, and other ecosystems, was one of the pioneers of prescribed burning. Since it conducted its first prescribed burn on a North Dakota prairie in the 1970s, the Nature Conservancy has expanded its prescribed burning program to a current level of over 40,000 acres (16,400 ha) of native habitat each year. The organization's objectives are controlling invasive plant species and maintaining the vigor of native fire-adapted plant communities.

Controversy over Prescribed Burns

Prescribed burning is controversial for several reasons. First, decades of education about fire suppression, both in the general public and among land management professionals, makes burning seem intuitively wrong to many people. Cultural icons such as Smokey Bear and Bambi, both fictional characters who suffered from forest fires, have symbolized the trauma and destruction of fires. The idea that fire might rejuvenate a forest is often harder to explain than the idea that fire destroys a forest. Second, people living near forests and grasslands fear that a controlled burn may escape and damage their property--an event that occurs rarely but is always a potential risk. Property owners are understandably nervous about the possibility of a fire escaping. On the other hand, prescribed burns have sometimes been used to protect property. A number of homes adjacent to the Wenatchee **National Forest** in Washington State were spared from the Tyee Creek fire of 1994 because previous burns had reduced fuel levels in the surrounding forest.

In addition to objections to fire danger, the **smoke** resulting from a prescribed fire is unpleasant and sometimes hazardous. There can be a real health risk for people with

Prescribed burning of a prairie in South Dakota for land management purposes. (Photograph by Stephen J. Krasemann. National Audubon Society Collection/Photo Researchers, Inc. Reproduced by permission.)

lung ailments or **asthma** if they are exposed to concentrated smoke. In addition, a deliberately set fire often violates **air quality** laws, making fires technically illegal in many populated areas. If the fire occurs near a road, **visibility** is also reduced, so that the road must often be closed while a burn is in progress. Although the smoke produced by a series of prescribed fires may be less than the smoke from a single large wildfire, prescribed fires are sensitive because the individual or group responsible for the fire is also liable for any damage or injury it causes.

Controversy over the use of prescribed burns has become especially serious in areas where human settlement is encroaching on natural areas. Where cities and suburbs spread into forested areas or reach the edges of preserves that are managed with fire, residents of new subdivisions usually object to the potential risks and inconvenience imposed by fire near their property. This problem is especially severe in the **chaparral** country of southern and central California. Chaparral is a fire-adapted ecosystem with highly combustible, dry vegetation that normally burns as every 30 years or so. As suburban development, with its high real estate values, moves into the chaparral, the economic and environmental costs of fire control have risen sharply. In wildlife and habitat preserves near metropolitan areas land managers have sometimes had to abandon successful fire management programs because of suburban sprawl.

President's Council on Sustainable Development

An environmental advisory group created by President Bill Clinton in June 1993 to develop new approaches for combining environmental protection in the United States with economic development. The council is composed of 25 members drawn from government, industry, and environmental groups. One of the primary mandates of the President's Council on **Sustainable Development** is to develop plans for the United States to fulfill its role in the **biodiversity**, global warming, and other accords negotiated at the 1992 **United Nations Earth Summit**.

Price-Anderson Act (1957)

The Price-Anderson Act, passed in 1957, limits the liability of civilian producers of **nuclear power** in the case of a catastrophic nuclear accident. In the case of such an accident, damages would be recovered from two sources: private insurance covering each plant and a common fund created by contributions from each nuclear power plant. This common fund would cover the difference in damages between the private insurance and the liability limit.

The act, named for its chief sponsors, Senator Clinton Anderson (NM) and Representative Melvin Price (IL), was passed to encourage private investment in nuclear power production. It was part of a general strategy to encourage and stimulate nuclear power production in the private sector. Without such liability limitations, the risk of nuclear power for utilities and manufacturers would be too great. Private insurance companies were not willing to underwrite the risks

due to the uncertainty involved and the potential magnitude of damages.

The law requires the private operators to carry the maximum amount of private insurance available ($65 million in the late 1950s). The upper limit for liability was set at $560 million per accident for personal damages, with the common fund covering the difference (between $65 million and $560 million). Once the liability limit is reached this law protects the operator from further financial liability. In addition to setting liability limits, the law establishes a common fund for victims to draw on if the utility did not have the ability to pay damages up to the liability limit. In return for this limited liability, utilities had to accept sole responsibility for accidents; equipment manufacturers would not be liable for any damages.

The Price-Anderson Act serves as a subsidy to the nuclear power industry. If it were not for this liability limitation, it is unlikely that any private firms would have become involved in the production of nuclear power. As a further incentive to private industry, the federal government set the liability limits at a very low level. This was done despite a 1957 government estimate of the damages due to a catastrophic accident: 3,000 immediate deaths and $7 billion in property damage.

In 1977, the Carolina Environmental Study Group filed a lawsuit, claiming that the Price-Anderson Act was unconstitutional because it was a taking of private property without just compensation, a violation of the Fifth Amendment. If a nuclear accident did occur and compensation was limited, the argument went, a taking of private property had occurred and compensation was limited in advance. A federal district court ruled for the environmental group: the act was unconstitutional. In 1978, however, the Supreme Court overturned this ruling, maintaining the constitutionality of the Price-Anderson Act.

The 1988 amendments to the act increased the liability limit per accident from $720 million to $7.2 billion, with the utilities continuing to contribute to a common fund to help pay for any damages if a major accident did occur. The private insurance coverage was set at $160 million per plant, with the common fund to make up the over $7 billion difference. These liability limits will last through 2003. Despite this tremendous increase in liability limits, the nuclear power industry was pleased to retain any liability limit in the face of significant opposition. The amendments also protect **U.S. Department of Energy** nuclear contractors from damage claims and limit the liability for nuclear waste accidents to $7 billion. *See also* Environmental law; Environmental liability; Nuclear fission; Radioactive waste; Radioactivity; Three Mile Island Nuclear Reactor

Primary pollutant

Primary pollutants cause **pollution** by their direct release into the **environment**. The substance released may already be present in some quantities, but it is considered a primary pollutant if the additional release brings the total quantity of the substance to pollution levels. For example, **carbon dioxide** is already naturally present in the **atmosphere**, but it becomes toxic when additional releases cause it to rise above its natural concentrations. The rise in levels of **carbon** dioxide is one contributing factor to the **greenhouse effect**.

The direct release into the atmosphere of a chemical that is not normally present in the air is also classified as a primary pollutant. **Hydrogen** fluoride, for example, is released from some coal-fired furnaces, but the compound is not usually present in unpolluted air.

A primary pollutant can be generated by many sources: **pesticide** dust sprayed intensively in agricultural areas, emissions from car and industrial exhausts, or dust kicked about from mining operations, to name a few. Some primary pollutants are composed of **particulate** matter that is not easily dispersed. **Smoke**, soot, dust, and liquid droplets released into the air either by the burning of fuel or other industrial or agricultural processes, are considered primary pollutants.

Primary pollutants also originate from natural sources. Volcanic ash, as well as grit and dust from volcanic explosions belong to this category. Salt dust blown inland by strong oceanic winds or gaseous pollution that originates from bogs, marshes, and other decomposing matter can also be classified as primary pollutants.

When two or more primary pollutants react in the atmosphere and cause additional atmospheric pollution, the result is called secondary pollution. **Nitrogen oxides**, for instance, can react with volatile organic compounds to from **smog**, a secondary pollutant. *See also* Air pollution; Air pollution index; Air quality criteria; National Ambient Air Quality Standard

Primary productivity (gross and net)

Primary producers (or autotrophs) are organisms that synthesize their own biochemical constituents using simple inorganic compounds and an external energy source to drive the process. The amount of energy fixed by autotrophs is known as primary production, and the rate of fixation is primary productivity. Both primary productivity and primary production may be measured in units of **carbon dioxide** (CO_2) fixed, energy fixed (as calories or joules), or **biomass** produced. Productivity in terrestrial ecosystems is often expressed in such units as kilograms of dry biomass (or its energy equivalent) per hectare per year (e.g., kg/ha.yr or kJ/ha.yr), while aquatic productivity is often measured on a volumetric basis (e.g., kg/m^3.yr). Many studies have been made of the primary productivity of various kinds of ecosystems.

Most primary producers are photoautotrophs that use sunlight as the external source of energy to drive **photosynthesis**. Photoautotrophs capture solar radiation using photosynthetic pigments, such as chlorophyll. Green plants are the most abundant photosynthetic organisms, along with algae and some bacteria. A much smaller number of autotrophs are chemoautotrophs, which capture some of the energy content of certain inorganic **chemicals** to drive their **chemosynthesis**. For example, *Thiobacillus thiooxidans* is a bacterium that oxidizes sulfide minerals to sulfate, utilizing some of the energy liberated during this reaction to drive its chemosynthesis.

The total fixation of solar (or chemical) energy by primary producers within an **ecosystem** is known as gross primary production (or GPP). Some of this production is utilized by autotrophs in support of their own **respiration** (R). Respiration involves physiological functions needed to maintain organisms in a healthy condition. Its complex reactions involve the metabolic oxidation of biochemicals, which requires a supply of oxygen and releases **carbon** dioxide and water as waste products. Net primary production (NPP) refers to the fraction of gross primary production that remains after primary producers have utilized some of their GPP for their own respiration. In other words, NPP = GPP - R.

For example, studies of an oak-pine forest in New York found that the total fixation of **solar energy** by vegetation (i.e., the gross primary productivity) was about 48.1-thousand kilojoules per hectare per year. This fixation rate was equivalent to less than 0.01% of the input of solar radiation to the forest. Because the plants utilized 27.2-thousand kJ/ha.yr in support of their respiration, the net primary productivity was 20.9-thousand kJ/ha.yr, occurring as the accumulating biomass of trees.

The NPP of primary producers supports the productivity of all other organisms, known as heterotrophs, in ecosystems. Heterotrophs can only utilize living or dead biomass as food, and they rely on other organisms to supply this fixed energy. Animal heterotrophs that feed on plants are known as herbivores (or primary consumers). Animals that kill and eat other animals are known as carnivores (or secondary consumers). Animals that feed on both plant and animal biomass are known as omnivores. Many heterotrophs feed on dead organic matter, and are called **decomposers** or **detritivores**.

Primary standards

Primary standards are numerical limits of allowable air and water pollutants designed to protect human health but not necessarily other parts of the **environment**. Primary standards differ from **secondary standards**, which are those that protect against all adverse effects on the environment, such as those on animals and vegetation. While the term primary standards usually relates to **air pollution** or **air quality**, there are federal primary standards for the drinking water supply.

The **Clean Air Act** is the major piece of legislation that protects and enhances the nation's air quality. As part of the act, Congress required the **Environmental Protection Agency** (EPA) to establish National Ambient Air Quality Standards (NAAQS) for air pollutants, which were characterized by wide dispersal and **emission** from many sources.

The NAAQS, or primary air quality standards, define the level of air quality to be achieved and maintained nation-

wide for six criteria pollutants: **sulfur dioxide**, **carbon monoxide**, **nitrogen oxides**, **ozone**, **particulate** matter, and **lead**. In general, these standards are not permitted to be exceeded more than once a year. In addition, the EPA is required to identify local hazardous air pollutants which could increase **mortality** or result in serious illnesses such as **cancer**, and establish national standards for them. Although hundreds of potentially hazardous air pollutants exist, only eight had been listed as of 1990: **mercury**, beryllium, **asbestos**, **vinyl chloride**, **benzene**, radioactive substances, coke oven emissions, and inorganic **arsenic**.

The Clean Air Act set a deadline of December 1987 for cities in the United States to meet federal primary standards. Some cities did meet the standards, increasing **automobile** emission inspections and instituting tighter regulations for incinerators, but some sixty cities could not comply. There has been a measurable increase in **nitrogen** oxide emissions in recent years, and more than 100 areas nationwide have exceeded standards at least part of the time for ozone and **carbon** monoxide levels. The EPA has estimated that 100 million people live in areas exceeding these standards. The most heavily-polluted areas of the **Los Angeles Basin**, Houston, and the New York corridor may take years to meet the air quality standards. Suggestions to hasten compliance have included plans to shut down industrial plants, ration gas, and restrict automobile use.

The 1990 Clean Air Act Amendments include provisions to tighten **pollution control** requirements in cities that have not attained the National Ambient Air Quality Standards. These provisions include, among others, requirements for stringent automobile **emission standards**. The new act also requires a 50 percent reduction in sulfur dioxide emissions, and it sets primary and secondary standards for dozens of **chemicals** that were not mentioned in the original act or amendments.

Primary standards are not consistent from country to country. For example, standards are defined for different average times, at varying numerical limits. In thirteen countries the sulfur dioxide standard ranges from 0.30 to 0.75 mg/m^3 for a 30-minute average, and from 0.05 to 0.38 mg/m^3 for a 24-hour average. Since **pollution** does not stay in once place, and since **acid rain** is often a source of controversy between bordering countries, the lack of international standards will continue to contribute to air pollution problems.

In the United States, concern about **water pollution** has resulted in higher standards for water cleanliness. These standards have been adopted by state and federal agencies, but the involvement of so many different agencies on different levels has contributed to a lack of agreement on some water standards.

The primary law to protect the integrity of the nation's water is the **Clean Water Act** (1972). The act requires the EPA to set **water quality** criteria based on the most recent scientific information. Under the Clean Water Act Reauthorization (1987), the EPA is required to publish revised water quality criteria, stress new programs to combat water pollution from toxics, and restrict waivers from national standards that had been easily obtained by discharges.

Criteria are not rules; they are a compilation of data about pollutants that can be used to formulate standards. Congress intended for the EPA to set the criteria and for the states to set the **water quality standards**. By 1990 the EPA had established criteria for 126 priority pollutants. Of these, 109 dealt with primary standards and thirty-four with secondary standards. But although these criteria have been published, few states have actually established standards for toxic pollutants or have incorporated these standards into the regulation of toxic **discharge**.

Under the Safe Drinking Water Reauthorization Act (1986), the EPA is not only required to set standards for contaminants in drinking water, but it also must monitor public drinking water for unregulated contaminants and set deadlines for the issuance of new standards. By 1990, the EPA had set primary standards for drinking water that covered the inorganic chemicals arsenic, barium, **cadmium**, chromium, lead, mercury, nitrate, selenium, silver, and fluoride. Primary drinking water standards are measured in terms of maximum contaminant levels (MCLs), which are the maximum permissible level of a contaminant in water at the tap; they are health related and legally enforceable.

Organic chemicals regulated by primary standards for drinking water include the pesticides Endrin, Lindane, Methoxychlor, and **Toxaphene**; the herbicides **2,4-D** and **2,4,5-T** Silvex; and the organics benzene, carbon tetrachloride, p-dichlorobenzene, 1,2-dichlorobenzene, 1,2-dichloroethane, 1,1-dichloroethylene, 1,1,1-trichloroethane, trichloroethylene, vinyl chloride, and an organic compound referred to as total **trihalomethanes**. Microbiological standards for drinking water have been set for coliform bacterium such as ***Escherichia coli***, which is present in sewage and which can cause gastroenteric infections, dysentery, hepatitis, and other diseases. Standards have also been set for turbidity, the murkiness of treated water that can interfere with disinfection processes. Radionuclides regulated by primary standards include beta particles and photon activity, gross alpha particles, and Radium-226 and -228.

As is the case with primary standards for air quality, an international comparison of primary standards for drinking water reveals a collection of confusing numbers. While the United States and Canada seem to agree on standards for organic compounds, this is where the similarity ends. As of 1990, the Canadian government had no primary drinking

water standards for radionuclides other than radium, and it had not set primary standards for volatile organic chemicals such as benzene and vinyl chloride. By 1990, the European Economic Community had set primary drinking water standards only for total pesticides and trihalomethanes. The World Health Organization (WHO) has recommended primary standards only for the organics 2,4-D, methoxychlor, and trihalomethanes, beta and alpha radionuclides, and five of the eight volatile organic chemicals regulated in the United States.

In the United States, there is evidence that primary standards regarding air and water pollutants have had some impact on air and water quality. Some of the nation's surface waters have improved since the implementation of the Clean Water Act. **Coliform bacteria** counts and **dissolved solids** have been reduced, and **dissolved oxygen** levels have increased enough to permit the reestablishment of plants and animals that had died out in polluted waters.

Air quality standards have led to an overall 20 percent reduction in emissions of particulates, sulfur dioxide, and carbon monoxide during the 1980s. Los Angeles, which suffers as much or more than any American city from air pollution, has proposed an air quality plan that would surpass the EPA's standards, requiring lifestyle changes to help combat air pollution.

Implementing laws and regulations to enforce water and air standards that will protect the health of humans will be expensive: The yearly price tag just for implementation of the Clean Air Act of 1990 is estimated to be $25 billion. But many believe the savings in health costs and environmental damage to be incalculable. *See also* Air pollution index; Air Quality Control Region; Air quality criteria; Attainment area; Nitrates and nitrites; Nonattainment area; Radioactive waste; Safe Drinking Water Act; Sewage treatment; Toxic substance

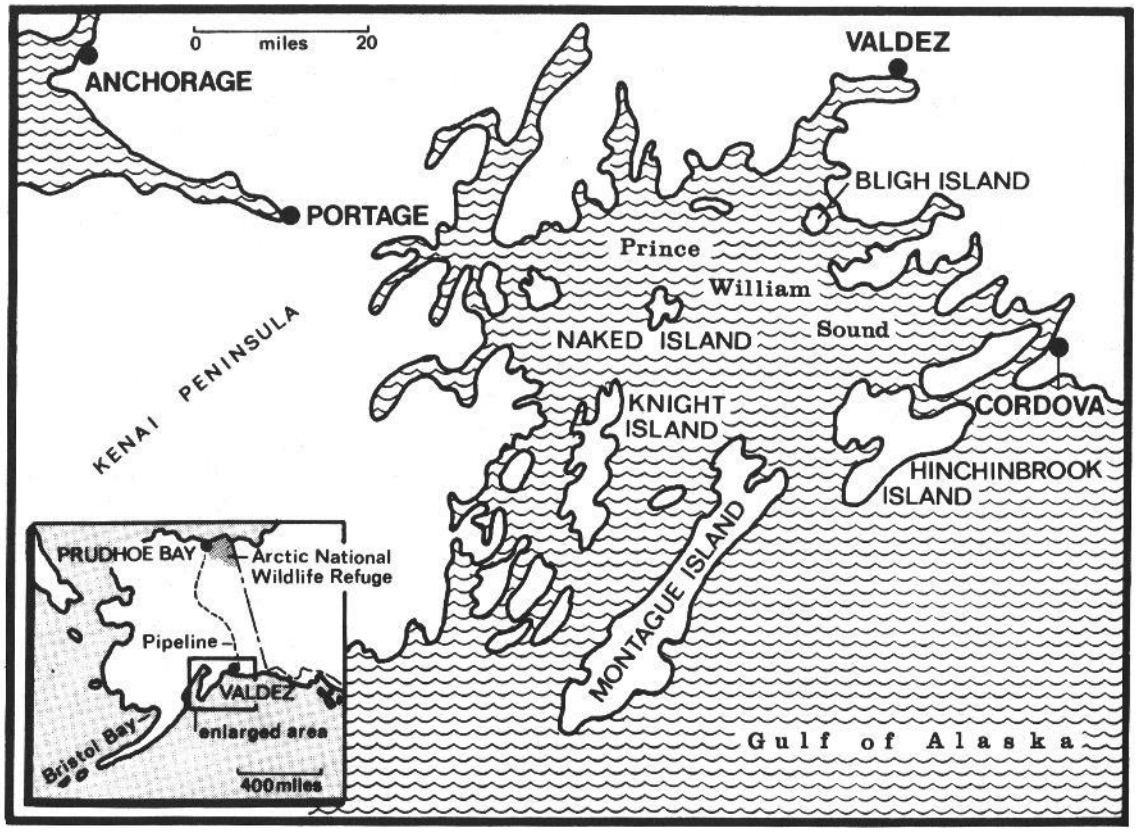
Prince William Sound

British explorer Captain James Cook made the European discovery of Prince William Sound in 1778. Today, the 25,090-square-mile (65,000-square-kilometer) passage southeast of Anchorage, Alaska, is the focal point of an ongoing political and environmental issue: whether oil can be safely transported in extreme climates without seriously threatening terrestrial and marine habitats or the recreational, agricultural, and industrial interests of the region.

Prince William Sound is bordered on the north and west by the Chugach and Kenai mountain ranges, on the east by the **Copper** River, and by the Hinchinbrook Islands on the south. Ten percent of its area is open water, with depths ranging from 492-2,952 ft (149-895 m). The remainder consists of shallow coastal waters, shoals, and reefs. The combined 2,980 miles (4,800 km) of mainland and island shoreline are home to more than 200 **species** of birds, among them approximately 3,000 bald eagles. Ten species of marine mammals, including **sea lions**, **seals**, **whales**, porpoises, and some 10,000 sea otters thrive in its bountiful waters. The natural beauty of Prince William Sound is responsible for the area's healthy tourism industry.



The Sound is world-renowned for its **salmon** fishery. More than 300 streams are used by salmon for spawning and, combined with hatchery inputs, more than one billion fry are released annually into the Sound. The herring season brings in an additional 12 million dollars to the area each year. The inhabitants of the four communities on the Sound are supported primarily by fishing and its related industries. For economic reasons, residents of the area are concerned with preserving the Sound's **natural resources**.

In the mid-1970s, the Cordova Island fishermen fought the oil industry's plan to build an oil pipeline from Prudhoe Bay in northern Alaska to Prince William Sound. The decision was left to the United States Senate which, despite warnings from scientists and environmental groups, voted to approve the proposed pipeline route into the Sound.

Natural and man-induced disasters threaten the health of the Sound. The Alaskan coast makes up the western boundary of the North American continental plate and is, therefore, subject to considerable seismic activity. On March 24, 1964, an **earthquake** centered in the mountains surrounding Prince William Sound had substantial effects on the Sound. Twenty-five years later to the day, the oil tanker ***Exxon Valdez*** wrecked on the rocks of the Sound's Bligh Reef in waters less than 39 ft (12 m) deep. Approximately 265,000 barrels (42 million liters) of heavy crude oil leaked into the Sound, one of the worst oil spills in United States history. The local **sea otter** population was nearly destroyed; many pelagic and shore bird populations were also heavily impacted. Effects of the spill and subsequent clean-up efforts on shoreline and seafloor communities are unknown, as are the long-term effects on Prince William Sound and adjacent habitats.

Priority pollutant

Under the 1977 amendments to the **Clean Water Act**, the **Environmental Protection Agency** is required to compile a list of priority toxic pollutants and to establish toxic pollutant **effluent** standards. A list of 126 key water pollutants was produced by EPA in 1981, and is updated regularly, with the updates appearing in the *Code of Federal Regulations*. This list, consisting of metals and organic compounds and known as the Priority Toxic Pollutant list, also prescribes numerical **water quality standards** for each compound. State **water quality** programs must use these standards or develop their own standards of at least equal stringency.

Privatization movement

This movement, initiated and supported primarily by economists, peaked in the early 1980s. Public ownership of land was inefficient because the administration of the lands was removed from the incentives and discipline of the free market. The case for the transfer of these lands to the private sector was made most strongly for lands managed for commodities (e.g., grazing lands, mineral lands, timber lands), but some also advocated transferring **wilderness** lands to the private sector, where it, too, would be more efficiently managed. Many of the economists who supported the program were a part of a movement referred to as the New Resource Economics (NRE), which advocated an increased reliance on private property rights and the free market for managing **natural resources**. Such an approach meshed

well with the Reagan Administration's philosophy of free market economics.

The privatization idea moved from theory to practice in February 1982 at a Cabinet Council on Economic Affairs meeting with the creation of the Asset Management Program. This program was designed to identify federal property for disposal, to develop legislation needed to dispose the land, and to oversee the sale of the land. The program was formalized by President Reagan in February 1982. The Fiscal Year (FY) 1983 budget proposal called for the sale of 5 percent of the nation's land (excluding Alaska), approximately 35 million acres, over five years. The revenues projected from the program were $17 billion from FY 1983 through FY 1987, the bulk of which was to come from sales of **Bureau of Land Management** (BLM) and **Forest Service** lands.

The BLM began to develop a program for land disposal, but in July 1983, Secretary of the Interior James Watt removed Interior Department lands from the Asset Management Program. He thought that the program was a mistake and was undermining the President's support in the West that had developed through the *good neighbor* program (which had defused the **Sagebrush Rebellion**).

In the summer of 1982, the Forest Service began to identify possible lands for disposal and announced that it would seek legislative authority to dispose the land. In March 1983, the agency announced that it would seek legislative authority to dispose of up to 6 million acres of land managed by the Forest Service (3.2% of the lands in the system). At this time, they indicated the specific amounts of land under consideration for disposal in each state, with high figures of 872,054 acres in Montana and 36 percent of its land in Ohio.

Opposition to the Asset Management Program was immediate and intense. The chief opponents were environmentalists, but they were also joined by the forestry profession and many western politicians. This already strong opposition to the program intensified once the specific areas for disposal were identified. In the face of this intense opposition, the Forest Service never presented legislation to Congress to allow the sale of these lands. The attempt to put privatization into practice was aborted by early 1984.

Probability

Probability is a quantity that describes the likelihood that an event will occur. If an event is almost certain to occur, the probability of the event is high. If the event is unlikely to occur, the probability is low. Probability is represented in **statistics** as a number between one and zero, and is derived from the ratio of the number of potential outcomes of interest to the number of all potential outcomes. For example, if there are 52 cards in a deck and a card player is equally likely to draw any card, then the probability of drawing hearts is 1/4 or 0.25%. The probability of drawing a king is 4/52 or 0.0769%. An event that has a probability of one will always occur and an event that has a probability of zero will never occur.

[*Marie H. Bundy*]

Project Eco-School

Project Eco-School (PES) is a nonprofit resource center designed to promote **environmental education** by serving as a link between schools and a vast library of environmental information. PES was founded in 1989 by Jayni Chase and her husband, comic-actor Chevy Chase, who were determined to foster greater environmental awareness by educating children.

Since its inception, PES has worked most closely with schools and children in California. In Inglewood, for instance, PES provided Worthington Elementary School with an environmental library. The organization has also been instrumental in developing consumer responsibility among students. It promoted the Zero Waste Lunch, in which students were encouraged to use reusable containers and avoid using the more wasteful, disposable, and prepackaged single-serving containers. The PES flyer "Guidelines for Packing a Zero Waste Lunch" provided tips on **recycling** and stressed the importance of our actions and choices on the **environment**.

Among PES's notable publications is*Blueprint for a Green School*, a reference book geared toward educating young people about a host of environmental issues, including recycling, **waste reduction**, and consumer alternatives. In addition,*Blueprint for a Green School* provides instruction on developing letter-writing campaigns and organizing a range of schoolchildren's activities such as field trips, community services, and fund raising.

The newsletter*Grapevine* is an important element in PES's endeavor to promote environmental awareness. A typical issue provides coverage of events and environmental activism in various schools throughout the country and reports on **environmental policy** affecting the nation and the

world. The newsletter also functions as a valuable networking tool by providing readers with coverage of recent developments in environmental laws and publications. An "Eco-Stars" segment details events relating to recently created organizations, especially those directed to students.

Propellants

Propellants are used to disperse aerosols, powders and other materials in a wide variety of applications. Consumers are familiar with products such as cleaners, waxes, and spray paints that are packaged in "aerosol spray cans" that use propellants. In addition, many medical, commercial and industrial products use propellants. These products include adhesives; document preservation sprays; portable fire extinguishing equipment; insecticides; sterilants; animal repellants; medical devices such as anti-asthma inhalers and topical anesthetic applicators; lubricants, coatings and cleaning fluids used in the electrical, electronic, and aerospace industries; and blowing agents and mold release agents used in the production of foams, plastic and elastomeric materials. In many cases, the propellant pressurizes, atomizes and delivers the product as an **aerosol** spray. In other cases, the propellant itself is the sole or major "active ingredient" of the product, usually for solvent and/or cleaning applications.

Aerosol sprays and other dispersions made possible using propellants can form very small and uniform droplets with controllable properties. These characteristics are desirable or necessary in critical applications where a very thin layer or coating must be applied to a surface, e.g., as a lubricant coating in an aerospace application. Additionally, the small aerosols can be inhaled deeply into the lung and the droplet itself may evaporate quickly, depending on the product. Such characteristics help optimize the delivery of drugs using medical inhalers.

The ideal propellant should generate sufficient volume and pressure of vapor or gas for a particular application, should be safe to humans and the **environment**, inert with respect to reactions with other materials, miscible or highly soluble in the product, easy to handle, and inexpensive. Each chemical has its own physical and chemical properties that affect the selection of a propellant for a given product and application. Important properties are solvency, performance, cost, and environmental considerations. Many of these properties are well characterized. For example, the solvency of a propellant can be measured as its solubility in water or other **chemicals**. Performance properties include the amount and pressure of vapor generated from the liquid, measured as vapor pressure, the volume of vapor generated per mass or volume of the liquid, and the ratio of the volume of gas to the volume of liquid. Performance also includes the range of temperatures where the propellant will function adequately, measured as the boiling and freezing points of the propellant, and as the vapor generation rates at different temperatures. The flammability of the propellant is another often critical property, measured as the flammability limits in air and the flash point. Additional properties that may be important include the density of the liquid and gas, the critical temperature and pressure, the specific heat of gas and liquid, the heat of vaporization, the viscosity of the liquid propellant, the coefficient of liquid expansion, and the surface tension. Environmental characteristics of propellants include the toxicity (often measured as **cancer** causing potency), the **ozone** depleting potential, the greenhouse warming potential, and the reactivity (in terms of forming ground level ozone). It is the environmental considerations that have brought propellants forward in the last 20+ years as an national and international environmental issue.

Restrictions on the Use of Propellants

Prior to the late 1970s, aerosol propellants were frequently chlorofluorocarbon (CFC) propellants, and this use constituted over 50% of total U.S. CFC consumption. At the time, the most widely used CFCs were CFC-11 and CFC-12. (These chemicals were also used in refrigeration, foam blowing, and sterilization). Following concerns raised in 1974 regarding possible stratospheric ozone depletion resulting from CFCs, the U.S. **Environmental Protection Agency** (EPA) and the **Food and Drug Administration** (FDA) acted on March 17, 1978, to ban the use of CFCs as aerosol propellants in all but essential applications. This reduced aerosol use of CFCs by approximately 95% and achieved nearly a 50% reduction in the U.S. consumption of CFCs. This reduction was largely accomplished without economic penalty as consumers voluntarily responded to advertising for "ozone safe" substitutes. Also in the late 1970s, Canada and a few Nordic nations banned or restricted aerosol propellant uses, also resulting in a sharp drop in their total CFC use. Later in the 1980s, however, increases in other uses of CFCs, largely as solvents, offset the earlier decreases.

The 1978 ban specifically exempted certain products based on a determination of essentiality. Also excluded were products where the CFC itself was the active ingredient or sole ingredient in an aerosol or pressurized dispenser products, as this did not fit the ban's narrow definition of an "aerosol" propellant. These restrictions remained in effect until 1990. Title VI of the 1990 **Clean Air Act** Amendments (CAAA) included provisions relevant to use of ozone deplet-

ing chemicals used as propellants and expanded restrictions for propellants. EPA's response is the "Significant New Alternatives Policy" (SNAP) Program which includes the evaluation of alternatives to ozone-depleting substances, including an assessment of their **ozone layer depletion** potential, global warming potential, toxicity, flammability, and exposure potential (section 612 of the CAAA; 59 FR 13044).

In general, ozone-depleting substances are divided into two classes with different product bans (section 610 in the CAAA): Class I comprises CFCs, **halons**, **carbon** tetrachloride, methyl chloroform (MCF), hydrobromofluorocarbons and methyl bromide; and Class II comprises solely of **hydrochlorofluorocarbons** (HCFCs). EPA is to prohibit the sale or distribution of certain "nonessential" products (as determined by Congress and EPA) that release class I substances, mandate the phaseout of class I and class II substances (sections 604 and 605), review substitutes (section 612), and prohibit the sale of certain nonessential products made with class I and class II substances (section 610). After its review, EPA issued regulations on January 15, 1993 (58 FR 4767) which banned CFC propellants in aerosols and other pressurized dispensers (and also in some other products such as flexible and packaging foam). Exceptions were made for a number of products, including certain medical devices; lubricants for pharmaceutical and tablet manufacture; gauze bandage adhesives and adhesive removers; topical anesthetic and vapocoolant products; lubricants, coatings and cleaning fluids for electrical and electronic equipment and aircraft maintenance that contain CFC-11, CFC-12 or CFC-113; release agents for molds used to produce plastic or elastomeric materials that contain CFC-11 or CFC-113; spinnerette lubricant/cleaning sprays used to produce synthetic fibers that contain CFC-114; CFCs used as halogen **ion** sources in **plasma** etching; document preservation sprays that contain CFC-113; and red pepper bear repellant sprays that contain CFC-113. However, these products are not exempted from the phase-out requirements for CFCs.

HCFCs can make excellent propellants, but their use has been limited due to their cost and restrictions regarding the class II ozone-depleting substances. In 1993, as a result of increased taxation and CFC phase-out, HCFCs were temporarily economically viable in applications where flammability is a concern and cheaper alternatives (**hydrocarbons**) could not be used. However, section 610(d) of the CAAA prohibits the sale or distribution of aerosol or foam products that contain or are manufactured with class II substances after January 1, 1994. Again, exceptions and exclusions from this ban have been made for "essential uses," i.e., if necessary due to flammability or worker safety issues and if the only available alternative is the use of a class I substance. On December 30, 1993, EPA published a final rule (58 FR 69637) which exempted medical devices, lubricants, coatings or cleaning fluids for electrical, electronic equipment, and aircraft maintenance, mold release agents used in the production of plastic and elastomeric materials and synthetic fibers, document preservation sprays containing HCFC-141b or HCFC-22, portable fire extinguishing equipment sold to commercial users, owners of boats, noncommercial aircraft, and wasp and hornet sprays for use near high-tension power lines. However, no other exceptions for class II propellants were made since substitutes are available.

Propellant Alternatives and Substitutes

Due to the restrictions on propellants use, a large number of propellant alternatives and substitutes have been investigated. Both EPA and industry have been active in this area.

Many products can be effectively packaged, distributed and used without employing a propellant. For example, some products are now sold for direct application as liquids or use manually operated finger and trigger pumps, two-compartment aerosol mechanism, mechanical pressure dispenser systems, and nonspray dispensers (e.g., solid stick dispensers). The elimination of propellants altogether can be viable option for some products and applications. In other cases, however, this may not provide proper dispersal or accurate application of the product. Also, persons using manual pumps or sprays may become fatigued with the constant pumping motion and thus produce poor product performance. Because propellants are considered essential in a variety of uses, there remains a need to find propellants that are not environmentally damaging. Unfortunately, no propellant exists which has all favorable properties. For example, some CFC propellant substitutes, e.g., ammonia, butane and pentane, have problems with toxicity and flammability. There may be some essential applications for CFCs propellants for which no practical substitutes exist, and the use of CFC propellants in anti-asthma inhalers is a frequently cited example.

A variety of propellants are being considered or are being used as alternative propellants for class I and II controlled substances. Each alternative propellant has its own physical and chemical characteristics that influence its suitability for a given application. The primary substitutes for aerosol propellant uses of CFC-11, HCFC-22 and HCFC-142b are saturated hydrocarbons (C3-C6); dimethyl ether; compressed gases; and HFCs. A few EPA-approved alternative propellants are discussed below.

Of the hydrocarbons, butane, isobutane and propane may be used singly or in mixtures. All have low boiling points, are relatively nontoxic, inexpensive and readily available. (As with essentially any propellant, very high concentrations may result in asphyxiation because of the lack of oxygen.) However, these propellants are flammable and, for example, should not be used around electrical equipment if

sparks could ignite the hydrocarbon propellant. To reduce product flammability, hydrocarbons can be used with water-based formulations. In the United States, nearly 50% of aerosol propellants were using hydrocarbon propellants prior to 1978, and nearly 90% in 1979 as a result of the CFC ban. Propane/butane propellants have been used since 1987 in the Scandinavian market.

Dimethyl ether (DME) is a medium pressure, flammable, liquefied propellant generally used in combination with other propellants. Its properties are similar to the hydrocarbons.

Compressed gases, including **carbon dioxide**, **nitrogen**, air, and **nitrous oxide**, are used in applications where a nonflammable propellant is necessary. These gases are inexpensive, readily available, nonflammable (although certain temperatures and pressures of nitrous oxide may create a moderate explosion risk), relatively nontoxic, and industrial practices for using these substitutes are well established. Since these gases are under significantly greater pressure than CFCs and HCFCs, containers holding these gases must be larger and bulkier, and safety precautions are necessary during filling operations. Often, modifications must be made to use compressed gases as they require new dispensing mechanisms and stronger containers due to the greater pressure; their low molecular weights restrict certain applications; high pressure compressed gases dispel material faster which may waste product; compressed gases cool upon expansion; and finally, they are not well suited for applications that require a fine and even dispersion. At present, about 7-9% of the aerosol products use compressed gases, and their use is expected to grow.

Hydrofluorocarbons (HFCs) such as HFC-134a, HFC-125 and HFC-152a are partially fluorinated hydrocarbons, developed relatively recently and currently priced significantly higher than HCFC-22. HFCs are less dense than HCFC-22, but can provide good performance in applications (but not products such as noise horns, which require a more dense gas). HFC-134a and HFC-125 are nonflammable and have very low toxicity. HFC-152a is slightly flammable. All three HFCs have zero ozone depletion potential, but are potential **greenhouse gases** although their atmospheric residence times are short. Additionally, these HFCs are chemically reactive and they contribute to the formation of tropospheric ozone. In ozone nonattainment areas, state and local controls on VOCs may restrict the use of these products. HFCs may be combined with flammable propellants to reduce the flammability of the mixtures. HFC-134a and HFC-227a are possible alternative propellants in medical applications (currently using CFC-12 and CFC-114). Approvals from both FDA and EPA are needed for these applications.

[*Stuart Batterman*]

Public Health Service

The United States Public Health Service is the health component of the **U.S. Department of Health and Human Services**. It originated in 1798 with the organization of the Marine Hospital Service, out of concern for the health of the nation's seafarers who brought diseases back to this country. As immigrants came to America, they brought with them **cholera**, smallpox, and yellow fever; the Public Health Service was charged with protecting the nation from infectious diseases.

Today the Service helps city and state health departments with health problems. Its responsibilities include controlling infectious diseases, immunizing children, controlling sexually transmitted diseases, preventing the spread of tuberculosis, and operating a quarantine program.

The Centers for Disease Control in Atlanta, Georgia, is the Public Health Service agency responsible for promoting health and preventing disease.

Public interest group

Public interest groups may be defined as those groups pursuing goals the achievement of which ostensibly will provide benefits to the public at large, or at least to a broader population than the group's own membership. Thus, for example, if a public interest group concerned with **air quality** is successful in its various strategies and activities, the achieved benefit--cleaner air--is available to the public at large, not merely to the group's members. The competition of interest groups, each pursuing either its own good or its conception of the public good, has been an increasingly prominent feature of American politics in the latter half of the twentieth century.

There is no single, universally applicable definition or test of the public good, and thus there is often a great deal of disagreement about what happens to be in the public interest, with different public interest groups taking quite different positions on various issues. In any particular political controversy, moreover, there may be several quite different public interests at stake. For example, the question of whether to build a nuclear-powered generator plant may involve competing public interests in the protection of the **environment** from **radioactive waste** and other dangers, the maintenance of public safety, and the promotion of economic growth, among others.

Similarly, the question of who benefits from the activities of a public interest group can also be quite complicated. Some benefits that are generally available to the public may not be equally available or accessible to everyone. If **wilderness** preservation groups are successful, for example, in hav-

ing land set aside in, say, Maine, that land is in principle available to potential recreational users from all over the country. But people from New England will find that benefit much more accessible than people from another region.

The membership, resources, and number of active public interest groups in the United States have all increased dramatically in the previous twenty-five years. There are now well over 2,500 national organizations promoting the public interest, as determined from almost every conceivable viewpoint, in a wide variety of issue areas. Over 40 million individual members support these groups with membership fees and other contributions totalling more than $4 billion every year. Many groups find additional support from various corporations, private foundations, and governmental agencies.

This growth in the public interest sector has been more than matched by, and partly was a response to, a similar explosion in the number and activities of organized interest groups and other politically active organizations pursuing benefits available only or primarily to their own members. Public interest groups often provide an effective counterweight to the activities of these more narrowly-oriented associations.

The growth of interest group politics has not been without its negative consequences. Some critics argue that every interest group, including "public interest groups," ultimately pursues relatively narrow goals important mainly to fairly limited constituencies. A politics based on the competition of these groups may be one in which well-organized narrow interests prevail over less well-organized broader interests. It may also produce decreased governmental performance and economic inefficiencies of various types. Public interest groups, moreover, seem to draw most of their support and membership from the middle and upper economic strata, whose interests and concerns are then disproportionately influential.

Public land

Public land refers to land owned by the government. Most frequently, it is used to refer to land owned and managed by the United States government, although it is sometimes used to refer to lands owned by state governments. The U.S. government owns 262 million acres, about one eighth of the land in the country, the bulk of which is located in the western states, including Alaska. The lands are managed primarily by the **Bureau of Land Management**, the Department of Defense, the **Fish and Wildlife Service**, the **Forest Service**, and the **National Park Service**.

Public Lands Council

An important environmental debate is currently focused on the use of public lands by livestock owners, particularly owners of cattle and sheep. Historically, the federal government has sold leases and permits for grazing on **public land** to these individuals at very low prices, often a few cents per acre.

In recent years, many environmentalists have argued that cattle are responsible for the destruction of large tracts of rangeland in the western states. They believe the government should either greatly increase the rates they charge for the use of western lands or prohibit grazing entirely on large parts of it. In response, livestock owners have claimed that they practice good-land management techniques and that in many cases the land is in better condition than it was before they began using it.

The Public Lands Council (PLC) is one of the primary groups representing those who use public lands for grazing. It is a nonprofit corporation that represents approximately 31,000 individuals and groups who hold permits and leases allowing them to use federal lands in 14 western states for the grazing of livestock. Twenty-six state groups belong to the council, and in addition, the council coordinates the public lands policies of three other organizations, the National Cattlemen's Association, the American Sheep Industry Association, and the Association of National **Grasslands**.

The PLC also represents the interests of public land ranchers before the United States Congress. It lobbies and monitors Congress and various federal agencies responsible for grazing, water use, **wilderness**, **wildlife**, and other federal land management policies that are of concern to the livestock industry.

The council was founded in 1968 for the purpose of promoting principles of sound management of federal lands for grazing and other purposes. The council obtains its funds from dues collected by state organizations and by contributions from other organizations it represents. It has two classes

of membership. General members are those who belong to a state organization that contributes to the PLC or those who make individual contributions. Voting members are elected by the general membership of each state, which may have a maximum of four voting members. Voting members meet at least once each year to establish PLC policy.

The PLC maintains a 500-volume library at its offices in Washington, D.C. It also publishes a quarterly newsletter, as well as news releases on specific issues, and regular columns in various western livestock publications. The council has also sponsored workshops and seminars on issues of importance to users of federal lands.

The American Lands and Resources Foundation has been established as an arm of the council for the purpose of receiving charitable and tax-deductible contributions to be used for the education of the general public about the benefits of using federal lands for livestock grazing.

[*David E. Newton*]

Public trust

The public trust doctrine is a legal doctrine dealing with the protection of certain uses and resources for public purposes, regardless of ownership. These uses or resources must be made available to the public, regardless of whether they are under public or private control. That is, they are held in trust for the public.

The modern public trust doctrine can be traced back at least as far as Roman civil law. It was further developed in English law as "things common to all." This public trust was applied mostly to navigation: the Crown possessed the ocean, the rivers, and the lands underlying these bodies of water (referred to as *jus publicum*). These were to be controlled in order to guarantee the public benefit of free navigation.

In the United States, the public trust doctrine is rooted in *Illinois Central Railroad Co. v. Illinois* (1892). In this case, the Supreme Court ruled that a grant held by the Illinois Central Railroad of the Chicago waterfront was void because it violated the state's public trust responsibilities to protect the rights of its citizens to navigate and fish in these waters. In making this decision, the court relied on English common law and served to underscore the existence of the public trust doctrine in the United States.

As a trustee, the government (federal or state) faces certain restrictions in protecting the public trust. These include using the trust property for common purpose and making it available for use by the public; not selling the trust property; and maintaining the trust property for particular types of uses. If any of these responsibilities are violated, the government can be sued by its citizens for neglecting its trust responsibilities.

With the rise of the environmental movement, the public trust doctrine has been applied with greater frequency and to a broader array of subjects. In addition to navigable waters, the doctrine has been applied to **wetlands**, state and national parks, and fossil beds. This expanded use of the doctrine has led to increased conflict. On the ground, there has been growing conflict over the limitations of private property. Landholders who find their actions limited argue that the public trust doctrine is a way to mask indirect **takings** and argue that they deserve just compensation in return for the restrictions. Among legal scholars, there is concern that the public trust doctrine is not firmly grounded in the law and simply reflects the opinions of judges in various cases. Proponents of the public trust doctrine, however, argue that it is a useful vehicle to temper unrestricted private property rights in the United States. Indeed, it has been argued that if public trust rights exist in private property, then no takings can occur since the regulation is merely recognizing the pre-existing limitation in the property.

Puget Sound/Georgia Basin International Task Force

The Puget Sound/Georgia Basin **ecosystem** consists of three shallow marine basins: the Strait of Georgia to the north, Puget Sound to the south, and the Strait of Juan de Fuca that connects this inland sea to the Pacific Ocean. In addition to open water, the ecosystem includes islands, shorelines, **wetlands**, and the watersheds of several mountain ranges whose freshwater rivers dilute the salt water. This rich and diverse ecosystem spans the United States-Canadian border and is threatened by **population growth**, urbanization, agriculture, and industry. In addition to Pacific **salmon**, valuable ground fish, and marine mammals including orca **whales**, Puget Sound/Georgia Basin has three of North America's busiest ports—Seattle, Tacoma, and

Vancouver, British Columbia (B.C.). Already an estimated 58% of the coastal wetlands of Puget Sound and 18% of the Strait of Georgia wetlands, which provide vital **habitat** to fish and birds, have been lost to development.

The Puget Sound/Georgia Basin International Task Force was created 1992 by the B.C./Washington Environmental Cooperation Council to coordinate priority environmental efforts between the state of Washington and the Canadian province of British Columbia. The task force includes representatives from the U.S. **Environmental Protection Agency** (EPA), the U.S. **Fish and Wildlife Service**, the Northwest Fisheries Science Center, the Department of **Fisheries and Oceans Canada**, and the Department of **Environment Canada**. State and provincial representation include the Washington Departments of Ecology, Natural Resources, and Fish and Wildlife and the B.C. Ministries of Water, Land and Air Protection and Sustainable Resource Management (formerly combined under the B.C. Ministry of Environment, Lands and Parks). The task force also includes representatives from the Puget Sound **Water Quality** Action Team, the Northwest Straits Commission, the Coast Salish Sea Council, and the Northwest Indian Fisheries Commission. The task force is charged with addressing marine, near-shore, and shoreline environmental issues for the entire Puget Sound/Georgia Basin shared ecosystem, as well as identifying and responding to new issues that may affect the shared waters.

The task force pursues project funding and promotes communication and cooperation among federal, state, provincial, local, and tribal/aboriginal governments and groups. In 1994, a Marine Science Panel (MSP), made up of Washington and B.C. scientists, identified priority environmental issues to be addressed by the task force's working groups. The task force cooperates with government agencies on implementation of the working groups' proposals.

The MSP recommended that fish and **wildlife management** shift its goal from maximum sustainable harvest to **species** protection. To this end, the task force's highest priority issues are protecting marine life, establishing **marine protected areas** (MPAs), and preventing near-shore and wetland habitat loss and the introduction of exotic or non-indigenous species (NIS). The Task Force Work Group on Marine Protected Areas has conducted an assessment of Puget Sound MPAs. The B.C. Nearshore Habitat Loss Work Group has devised a plan for preventing coastal habitat loss in the Georgia Basin. The Washington Aquatic Nuisance Species Coordination Committee and the B.C. Working Group on Non-Indigenous Species have worked to develop nuisance species legislation and proposals for regulating ballast water release from ships, a major source of NIS introduction. In collaboration with various agencies, the task force has launched a public NIS education program.

The medium priority recommendations of the MSP included the control of toxic waste discharges and the prevention of large **oil spills** and major diversions of freshwater for **dams** and other projects. The Washington and B.C. toxic chemical work groups have undertaken research, inventoried contaminated sites, and assessed the movement of toxic **chemicals** through the shared waters.

On May 15, 2002 the Transboundary Georgia Basin-Puget Sound Environmental Indicators Working Group released their ecosystem indicators report, concluding that population growth constitutes the primary threat to the region. During the 1990s, the region's population grew by about 20% to seven million people. It is projected to grow another 32% by 2020. Whereas most of the growth during the 1990s was in urban areas, new growth is expected to occur in more rural areas. The report found that **air pollution** from inhalable particles has declined since 1994; the amount of waste produced per person has remained about the same; and **recycling** has increased, particularly in B.C. However the loss of stream and shoreline habitats to development is endangering the region's plants and animals. In the Georgia Basin almost 35% of the freshwater fish and 12% of the reptiles are in danger of **extinction**, as are 18% of Puget Sound's freshwater fish and 25% of its reptiles. The harbor **seals** of Puget Sound are much more heavily contaminated with **polychlorinated biphenyls** (PCBs) than the Strait of Georgia seals. PCB contamination levels have remained constant for more than 14 years, despite major cleanup efforts. The harbor seals also are contaminated with other **persistent organic pollutants** including dioxins and **furans**. The report found that most of the ecosystem's protected land is in the mountains: only 1% of land below 3,000 ft (914 m) is protected.

Pulp and paper mills

Pulp and paper mills take wood and transform the raw product into paper. Hardwood logs (beech, birch, and maple) and softwoods (pine, spruce, and fir) are harvested from managed forestlands or purchased from local farms and timberlands across the world and are transported to mills for processing. Hardwoods are more dense, shorter fibered, and slower growing. Softwoods are less dense, longer fibered, and faster growing.

Today, the process is mainly done with high tech, sophisticated machinery. Wood products, which consist of lignin (30 percent), fiber (50 percent), and other materials--carbohydrates, proteins, fats, turpentine, resins, etc., (20 percent) are transformed into paper consisting of fiber, and additives--clay, titanium dioxide, calcium carbonate, water, rosin, alum, starches, gums, dyes, synthetic polymers, and pigments. Wood is about 50 percent cellulose fiber. The structure of paper is a tightly bonded web of cellulose fibers. About 80 percent of a typical printing paper by weight is cellulose fiber. First in the process, the standard eight-foot (2.4-m) logs are debarked by tumbling them in a giant barking drum and then chipped by a machine that reduces them to half-inch chips. The chips are cooked, after being screened and steamed, in a digester using sodium bisulfite cooking liquor to remove most of the lignin, the sticky matter in a tree that bonds the cellulose fibers together. This is the pulping process.

Then the chips are washed, refined, and cleaned to separate the cellulose fibers and create the watery suspension called pulp. The pulp is bleached in a two-stage process with a number of possible **chemicals**. Those companies that choose to avoid **chlorine** bleach will use **hydrogen** peroxide and sodium hydrosulfite which yields a northern high-yield hardwood sulfite pulp. This pulp is blended with additional softwood kraft pulp after refining as part of the stock preparation process, which involves adding such materials as dyes, pigments, clay fillers, internal sizing, additional brighteners, and opacifiers.

Late in the process, the stock is further refined to adjust fiber length and **drainage** characteristics for good formation and bonding strength. The consistency of the stock is reduced by adding more water and the stock is cleaned again to remove foreign particles. The product is then pumped to the paper machine headbox.

From here, the dilute stock (99.5 percent water) flows out in a uniformly thin slice onto a Fourdrinier wire--an endless moving screen that drains water from the stock to form a self-supporting web of paper. The web moves off the wire into the press section which squeezes out more water between two press felts, then into the first drier section where more moisture is removed by evaporation as the paper web winds forward around an array of steam-heated drums. At the size press, a water-resistant surface sizing is added in an immersion bath.

From there the sheet enters a second drier section where the sheet is redried to the final desired moisture level before passing through the computer scanner. The scanner is part of a system for automatically monitoring and regulating basis weight and moisture. The paper enters the calendar stack, where massive steel polishing rolls give the sheet its final machine finish and bulking properties.

The web of paper is then wound up in a single long reel, which is cut and moved off the paper machine to a slitter/winder machine which slices the reel into rolls of the desired width and rewinds them onto the appropriate cores. The rolls are then conveyed to the finishing room where they are weighed, wrapped, labeled, and shipped.

In practice, all papers, even newsprint, are pulp blends, but they are placed in one of two categories for convenient description: groundwood and free sheet. And in practice, other pulp varieties enter into the picture. They may be reclaimed pulps such as de-inked or post-consumer waste; recycled pulps which included scraps, trim, and unprinted waste; cotton fiber pulps; synthetic fibers; and pulps from plants other than trees: bagasse, esparto, bamboo, hemp, **water hyacinth**; and banana, or rice. But the dominant raw material remains wood pulp. Paper makers choose and blend from the spectrum of pulps according to the demands on their grades for strength, cleanliness, brightness, opacity, printing, and converting requirements, aesthetics, and market price.

From cotton fiber-based sheets to the less expensive papers made from groundwood, to recycled grades manufactured with various percentages of wastepaper content, papermakers have consistently responded to the need of the marketplace. In today's increasingly environmentally conscious marketplace, papermakers are being called on to produce pulp that is environmentally friendly. Eliminating chlo-

rine from the bleaching process is a major step in eliminating unwanted **toxins**. The changeover costs money and is the source of controversy here in the United States.

However, the chlorine-free trend has taken a firm hold in Europe. All of Sweden requires its printing and writing paper mills to be chlorine-free by the year 2010. France, Germany, and several other countries have several mills that are reported to be chlorine-free and the trend is moving across Canada.

While there are growing exceptions, most North American mills still use a chlorine bleaching process to create a bright, white pulp. Why the need to eliminate the chemical?

In the bleaching process, chlorine, chlorine dioxide, and other chlorine compounds create toxic byproducts. These byproducts consist of over 1,000 chemicals, some of which are the most toxic known to man. The list includes: **dioxin** and other organochlorines compounds such as PCBs, DDT, **chlordane**, aldrin, dieldrin, **toxaphene**, chloroform, heptachlor and **furans**. These are formed by the reaction of lignin in the pulp with chlorine or chlorine-based compounds used in the bleaching sequence of all kraft pulps.

These unwanted chemicals byproducts must be discharged and end up in the **effluent**. The effluent is released into our rivers, lakes and streams and is threatening the **groundwater** and our drinking water, as well as the food chain through fish and birds. Epidemic health effects among thirteen **species** of fish and **wildlife** near the top of the **Great Lakes** food web have been identified. Not only are these toxic chemicals causing **cancer** and birth deformities in humans and wildlife, but they are very persistent, building up in our waterways and eventually into our bodies.

Dioxin traces have been found in papers and even in coffee from chlorine-bleached coffee **filters** and milk from chlorine-bleached milk cartons, as well as in women's hygiene products. Most of the paper being sold in the United States today as "dioxin free" is actually "dioxin undetectable." That is because dioxin can be measured in **parts per trillion** or parts per quintillion, but beyond that level, there are no scientific measurements sophisticated enough. Or if measurable, the process becomes very expensive. (If exposed often enough, even these minuscule quantities build up in the **environment** and in humans.) To be truly dioxin free, the paper must be made from pulps that have been bleached without chlorine or chlorine-based compounds.

The newer trend is to eliminate chlorine from the bleaching process completely. Some North American mills are turning to hydrogen peroxide, oxygen brightening, or **ozone** brightening. These compounds do not produce dioxin or other organochlorine compounds and are considered "environmentally-sound." The United States pulp and paper industry has sharply reduced its use of the chemical and plans to curtail use further during the next few years.

In part, this reduction can be traced to the increased sophistication of pulp and paper plants during the past decade. The cooking and bleaching operations have been fine-tuned. Wood chips are cooked more before they go to the bleach plant, so less bleaching is required. Also, in some plants, industry is trying chlorine dioxide as a substitute; it produces less dioxin, but still contains chlorine.

The result of these changes means an 80 percent reduction in the amount of dioxin associated with bleaching. Between 1988-1989, a total of 2.5 lb (11.1 kg) of dioxin was produced. As of 1993, that number fell below 8 ounces (22.7 g) per year. Eight ounces sound like a small amount, but scientists measure dioxin in **parts per million**, billion, trillion and quintillion, so eight ounces is still too high.

A number of lawsuits have been filed by residents living near or downstream of dioxin-contaminated pulp mills because of the health threats. The more the plaintiffs win, the sooner will the use of chlorine be eliminated completely. It is estimated that the amount of chlorine used in pulp and paper bleaching will fall from 1.4 million tons in 1990 to 920,000 tons by 1995.The eventual goal is **zero discharge**.

Purple loosestrife

Purple loosestrife (*Lythrum salicaria*) is an aggressive wetland plant **species** first introduced into the United States from Europe. It is a showy, attractive plant that grows up to 4 feet (1.2 m) in height with pink and purple flowers arranged on a spike, and it is common in shallow marshes and lakeshores all across the northern half of the United States.

Loosestrife is a perennial plant species that spreads rapidly because of the high quantity of seeds it produces (sometimes up to 300,000 seeds per plant) and the efficient dispersal of seeds by wind and water. The plant has a well-developed root system and is able to tolerate a variety of **soil** moisture conditions. This has made it an effective colonizer of disturbed ground as well as areas with fluctuating

Purpole loosestrife (*Lythrum salicaria*). (Photograph by John Dudak. Phototake. Reproduced by permission.)

hydrological regimes. Because of its attractive flowers, it has also been planted as an ornamental species.

As a highly adaptive and tolerant plant, loosestrife is often able to outcompete native plant species in many environments, particularly in **wetlands** and disturbed areas. Other species often have difficulty surviving once it becomes established, and loosestrife has low value as food and nesting **habitat**. For example, the cattail plants in many wetlands of New York state have been replaced by purple loosestrife. **Wildlife** experts prize cattails as plants whose roots and tubes are of high value as food source to small mammals and rodents, and the spread of loosestrife has led to a decline in the habitat values of these wetlands. So, in spite of its pleasing appearance, New York and a number of other states have embarked on purple loosestrife eradication programs.

The most commonly used chemical method for eradicating purple loosestrife is a **herbicide** known as Rodeo--a selective herbicide that kills only dicotyledonous or broadleaf plants. When a diluted solution of Rodeo is sprayed directly on mature leaves, it disrupts protein synthesis and causes plant death within two to seven days. Physical removal of the plants by mowing early in the growing season, prior to seed set, has also been effective in keeping areas free of loosestrife. *See also* Introduced species

Q

David Quaamen (1948 –)

American writer

Nature writing is a well established tradition in American literature, yet the label has in recent years come to be considered one-dimensional and even a little quaint by 'serious' writers and 'real' scientists. Many of the best nature writers are not trained ecologists and ecology is supposed to have out-grown natural history. Intellectuals belittle the popularity of nature writing and see themselves as beyond the backwoods genre.

Still, the American public continues to gain much of its understanding and awareness of natural systems, of environmental issues, and of humanity's threat to wild species and places from the best and most popular of the nature writers—Edwin Way Teale, Annie Dillard, Terry Tempest Williams...and David Quammen. Part of the exposure comes from the fact that many of these writers make a good part of their living by lecturing and 'reading' widely in popular venues. Quammen, however, considers his writing as departing "distantly from conventional nature writing, of which I have never much cared to be either a reader or an author." He started writing as a novelist, but, beginning in 1981, spent 15 years writing a column titled "Natural Acts," for Outside magazine, his job "to think about the natural world, and about human relationships with that world, in a way that would interest" the half million readers of the magazine, an assignment which he says allowed him "unimaginable freedom to explore a wide range of peculiar theories, remote places, bizarre facts, and unpopular opinions." His first collection of essays (*Natural Acts: A Sidelong View of Science and Nature*), mostly taken from his column, appeared in 1985. That collection was well received, with one reviewer suggesting that Quammen "breathes importance into the little-known nitty-gritty of biology" and in the process "describes wondrous places, people and situations."

Still, Quammen does write about nature, and though many of his essays are "very funny and very offbeat," (the word quirky is often used) they are just as frequently serious commentaries on science and its relationship to politics, philosophy, and a variety of other subjects. Perhaps then, it is more appropriate to use his own descriptor and call him a science journalist. Lee Dembart in the *Los Angeles Times* stated that "Quammen likes science for its own sake, but he also likes it for the larger truths it suggests. He works the fringes of science and draws conclusions that are universal."

Marilyn McEntyre, author of one of the most detailed looks to date at Quammen's work, is enthusiastic: Quammen's "gift to the general reader is to make science accessible, compelling, and, not least important, entertaining." Her comments underline the idiosyncrasies of Quammen's work: "Certainly Quammen is concerned with those central and urgent ethical dilemmas that define and unite what may loosely be known as the 'environmental movement,' but he also pauses to consider the ethics of domestic dog ownership," a reference to his questions about possible 'unnatural' harm to dogs from their confinement in urban and suburban areas, "daring to throw darts at one of the most sacred of American icons, 'man's best friend.'"

Born in Cincinnati, in 1948, and spending a childhood in southwest Ohio as the only boy of three children, he was the "designated mowist" of the family lawn, a repeated chore that probably had something to do with the "why lawns?" kinds of questions about human-nature relationships that appear so often in his writings . Quammen went on to earn a B.A. degree in English from Yale University in 1970, and, as a Rhodes scholar, a B. Litt. in 1973 from Oxford.

The *Song of the Dodo* (1996), one of Quammen's most recent, yet most recognized books, illustrates both his grasp of current ideas in science and the heat that he (and the scientists themselves) take when they relate those ideas to how "humans in all their variousness, regard and react to the natural world, in all its variousness." The variety in human-environment relationships is a basic theme Quammen claims for much of his writing. He built the popular book *Song of the Dodo*on the less publicly accessible island biogeography research of Robert MacArthur and E. O. Wil-

son, creating a sharp, clear depiction of the ideas that islands are bounded, isolated places vulnerable to extinctions, a vulnerability repeated as humans create "isolated, island-like enclaves" in terrestrial ecosystems, places too small, fragmented, and isolated to support diverse populations.

This mix of grave warnings of environmental degradation and species extinctions with personal anecdotes and popular travel writing draws both praise and criticism. His books are accessible to a wide audience, so the environmental issues he discusses are widely disseminated, increasing the public's awareness. Even reviews in biology journals like *BioScience* laud Quammen's island biogeography book as "a work in the finest tradition of autobiographical natural history," a history traced back to the great naturalists of the nineteenth century, including Darwin. But Quammen doesn't escape the general questions raised by critics of island biogeography theory of how different land 'islands' surrounded by land are from islands bounded by water.

Some critics think that Quammen's accessibility is based on the sugar-coating of information: "Quammen has succumbed to the fashionable conceit that 'popular' science has to be diluted with travelogue and soap biography." However, Bill McKibben, in *Audubon* magazine, echoed many others when he proclaimed *Song of the Dodo* a "masterpiece of scientific journalism...and a heroic achievement."

Rabbits in Australia

Imported into **Australia** in the mid-nineteenth century, rabbits have overrun much of the country, causing extensive agricultural and environmental damage and demonstrating the dangers of introducing non-native **species** into an area. Before the first humans arrived in Australia, the only mammals living there were about 150 species of marsupials as well as **bats**, rats, mice, platypuses, and echidnas. The chief predator in Australia today is the dingo, a wild dog introduced about 40,000 years ago by Australia's first human settlers, the Aborigines. When the British settled Australia as a penal colony in the late 1700s, they brought a variety of pets and livestock with them, including rabbits.

The problems with rabbits began in 1859, when 12 pairs of European rabbits were released on a ranch. Since no significant numbers of natural predators were present in Australia, the rabbit population exploded within a few years. They overgrazed the grass used for sheep raising, and despite extensive efforts to reduce and control the population, by 1953 approximately 1.2 million mi^2 (3 million km^2) were inhabited by between several hundred million and over one billion rabbits.

The rabbits have caused considerable damage to Australia's **environment**, especially its native plants and **wildlife**. Their extensive burrows cause **soil erosion**, and they eat large quantities of grass and shoots of other plants, devastating native **flora** that birds, insects, and other creatures depend on for food and cover.

Repeated attempts have been made to exterminate the rabbits and limit their populations, often by fumigating and ripping up their burrows, or by using poison bait. The most effective effort undertaken involved the introduction of myxomatosis in the 1950s, a disease that is fatal to rabbits. But after an initial decline, the rabbit population began to recover, and much of Australia remained overrun by the animals.

Proponents of eradication say that the most promising new biological agent to control wild rabbits is know as RCV (rabbit calicivirus), which is thought to be a new disease, and has killed farmed rabbits in China and Europe. In its early stages, it kills over 90% of infected rabbits. In the laboratory, it has been shown to kill rabbits shortly after infection; and after 31 different native species were exposed to the **virus**, it did not appear to be capable of infecting non-target animals. But the certainty of this is disputed by other scientists, who worry that release of the virus is "an uncontrollable and unpredictable" biological experiment; that it could eventually jump the species barrier, especially if it mutates into a different form; and that rabbits will eventually develop **resistance** to the virus, as they did to myxomatosis.

The elimination of rabbits might even have adverse consequences, such as removing an important food source from eagles and other predators who have come to depend on them. Wild dogs and cats, deprived of their normal prey, may turn to increased **hunting** of kangaroos and other marsupials. On the other hand, the number of feral canines and felines might decline with the demise of an easy and abundant food source, which would benefit marsupials. So, the ultimate impact of RCV is not entirely predictable.

There is little danger of an immediate collapse of the rabbit population. The latest data estimates that the population has been reduced from about 200–300 million rabbits to 100 million.

The proliferation of rabbits in Australia has cost the government and ranchers billions of dollars. This situation remains a primary example of the harm that can result from the introduction of non-native species, no matter how seemingly harmless, into a foreign environment.

Rachel Carson Council

The Rachel Carson Council focuses on the dangers of pesticides and other toxic **chemicals** and their impact on human health, **wildlife**, and the **environment**. After the 1962 publication of her classic book on pesticides, *Silent Spring*, **Rachel Carson** was overwhelmed by the public interest it generated, including letters from many people asking for advice, guidance, and information. Shortly after her death in April 1964, colleagues and friends of Carson established an organization to keep the public informed on new developments in the field of chemical contamination. Originally called the Rachel Carson Trust for the Living Environment, it was incorporated in 1965 to work for **conservation** of **natural resources**, to increase knowledge about threats to the environment, and to serve as a clearinghouse of information for scientists, government officials, environmentalists, journalists, and the public.

The Council has long warned that many pesticides, regulated by the **Environmental Protection Agency** (EPA) and widely used by homeowners, farmers, and industry, are extremely harmful. Many of these chemicals can cause **cancer**, miscarriages, **birth defects**, genetic damage, and harm to the central nervous system in humans, as well as destroy wildlife and poison the environment and **food chain/web** for years to come.

Other, less acutely toxic chemicals that are commonly used, the organization points out, can cause "delayed neurotoxicity," a milder form of nerve damage that can show up in subtle behavior changes such as memory loss, fatigue, irritability, sleep disturbance, and altered brain wave patterns. Concerning termiticides used in schools, "children are especially vulnerable to this kind of poisoning," the Council observes, "and the implications for disturbing their ability to learn are especially serious."

Through its studies, publications, and information distribution, the Council has provided data strongly indicating that many pesticides now in widespread use should be banned or carefully restricted. The group has urged and petitioned the EPA to take such action on a variety of chemicals that represent serious potential dangers to the health and lives of millions of Americans and even to **future generations**.

The Council has also expressed strong concern about, and sponsored extensive research into, the link between exposure to toxic chemicals and the dramatic increase in recent years in cancer incidence and death rates. The group's publications and officials have warned that the presence of dozens of cancer-causing chemicals in our food, air, and water is constantly exposing us to deadly carcinogens and is contributing to the mounting incidence of cancer, which eventually strikes almost one American in three, and kills over 500,000 Americans every year.

The Council publishes a wide variety of books, booklets, and brochures on pesticides and toxic chemicals and alternatives to their use. Its most recent comprehensive work, *Basic Guide to Pesticides: Their Characteristics and Hazards*

(1992), describes and analyzes over 700 pesticides. Other publications discuss the least toxic methods of dealing with pests in the home, garden, and greenhouse; non-toxic gardening; ways to safely cure and prevent lawn diseases; and the dangers of poisons used to keep lawns green.

The Council's board of directors includes experts and leaders in the fields of **environmental science**, medicine, education, law, and consumer interest, and a board of consulting experts includes scientists from many fields.

Radiation exposure

Radiation is defined as the **emission** of energy from an atom in the form of a wave or particle. Such energy is released as electromagnetic radiation or as **radioactivity**. Electromagnetic radiation includes radio waves, infrared waves or heat, visible light, **ultraviolet radiation**, x rays, gamma rays, and cosmic rays. Radioactivity, emitted when an atomic nucleus undergoes decay, usually takes the form of a particle such as an **alpha particle** or **beta particle**, though atomic decay can also release electromagnetic gamma rays.

While radiation in the form of heat, visible light, and even ultraviolet light is essential to life, the word "radiation" is often used to refer only to those emissions which can damage or kill living things. Such harm is specifically attributed to radioactive particles as well as the electromagnetic rays with frequencies higher than visible light (ultraviolet, x rays, gamma rays). Harmful electromagnetic radiation is also known as **ionizing radiation** because it strips atoms of their electrons, leaving highly reactive ions called *free radicals* which can damage tissue or genetic material.

Effects of radiation

The effects of radiation depend upon the type of radiation absorbed, the amount or dose received, and the part of the body irradiated. While alpha and beta particles have only limited power to penetrate the body, gamma rays and x rays are far more potent. The damage potential of a radiation dose is expressed in *rems*, a quantity equal to the actual dose in *rads* (units per kg) multiplied by a quality factor, called *Q*, representing the potency of the radiation in living tissue. Over a lifetime, a person typically receives 7–14 rems from natural sources. Exposure to 5–75 rems causes few observable symptoms. Exposure to 75–200 rems leads to vomiting, fatigue, and loss of appetite. Exposure to 300 rems or more leads to severe changes in blood cells accompanied by hemorrhage. Such a dosage delivered to the whole body is lethal 50% of the time. An exposure of more than 600 rems causes loss of hair, loss of the body's ability to fight infection, and results in death. A dose of 10,000 rem will kill quickly through damage to the central nervous system.

The symptoms that follow exposure to a sufficient dose of radiation are often termed "radiation sickness" or "radiation burn." Bone marrow and lymphoid tissue cells, testes and ovaries, and embryonic tissue are most sensitive to radiation exposure. Since the lymphatic tissue manufactures white blood cells (WBCs), **radiation sickness** is almost always accompanied by a reduction in WBC production within 72 hours, and recovery from a radiation dose is first indicated by an increase in WBC production.

Any exposure to radiation increases the risk of **cancer**, **birth defects**, and genetic damage, as well as accelerating the aging process, and causing other health problems including impaired immunity. Among the chronic diseases suffered by those exposed to radiation are cancer, stroke, diabetes, hypertension, and cardiovascular and renal disease.

Sources of radiation

Some 82% of the average American's radiation exposure comes from natural sources. These sources include **radon** gas emissions from underground, cosmic rays from space, naturally occurring radioactive elements within our own bodies, and radioactive particles emitted from **soil** and rocks. Man-made radiation, the other 18%, comes primarily from medical x rays and nuclear medicine, but is also emitted from some consumer products (such as **smoke** detectors and blue topaz jewelry), or originates in the production and testing of **nuclear weapons** and the manufacture of nuclear fuels.

Environmental scientists believe that radon, a radioactive gas, accounts for most of the radiation dose Americans receive. Released by the decay of **uranium** in the earth, radon can infiltrate a house through pores in block walls, cracks in basement walls or floors, or around pipes. The **Environmental Protection Agency** estimates that eight million homes in the United States have potentially dangerous levels of radon, and calls radon "the largest environmental radiation health problem affecting Americans." Inhaled radon may contribute to 20,000 lung cancer deaths each year in the United States. The EPA now recommends that homeowners test their houses for radon gas and install a specialized ventilation system if excessive levels of gas are detected.

Though artificial sources of radiation contribute only a small fraction to overall radiation exposure, they remain a strong concern for two reasons. First, they are preventable or avoidable, unlike cosmic radiation, for example. Second, while the *average* individual may not receive a significant

dose of radiation from artificial sources, geographic and occupational factors may mean dramatically higher doses of radiation for large numbers of people. For instance, many Americans have been exposed to radiation from nearly 600 nuclear tests conducted at the **Nevada Test Site**. From the early 1950s to the early 1960s, atmospheric blasts caused a lingering increase in radiation-related sickness downwind of the site, and increased the overall dose of radiation received by Americans by as much as 7%. Once the tests were moved underground, that figure fell to less than 1%.

A February 1990 study of the Windscale **plutonium** processing plant in Britain clearly demonstrated the importance of the indirect effects of radiation exposure. The study correlated an abnormally high rate of **leukemia** among children in the area with male workers at the plant, who evidently passed a tendency to leukemia to their children even though they had been receiving radiation doses that were considered "acceptable."

Recently, the EPA published their National Radon Results listing studies from 1984 to 1999. This study showed that 18 million homes have been tested for radon in the United States. In 1999 alone, there were about 1.4 million homes tested for radon. The knowledge of radon's harmful effects is on the rise (88% of Americans were aware of the harmful effects in 1999 compared to 73% in 1996) which is apparently contributing to the increase in testing.

Radiation sickness

Radiation sickness, also known as acute radiation syndrome or **ionizing radiation** injury, is illness resulting from human exposure to ionizing radiation. The **radiation exposure** may be from natural sources, such as radium, or from man-made sources, such as x rays, nuclear reactors, or atomic bombs. Ionizing radiation penetrates cells of the body and ultimately causes damage to critically important molecules such as nucleic acids and enzymes. Immediate cell death may occur if the dose of ionizing radiation is sufficiently high; lower doses result in cell injury which may preclude cell replication. Tissues at greatest risk for radiation injury are those which have cells that are rapidly dividing. Blood forming cells, the lining to the gastrointestinal tract, skin, and hair forming cells are particularly vulnerable. Muscle, brain, liver, and other tissues, which have a low rate of cell division, are less so.

Radiation Sources

Natural Sources	
Radon gas	55%
Inside body	11%
Rocks, soil, and groundwater	8%
Cosmic rays	8%
Artificial sources	
Medical x rays	11%
Nuclear medicine	4%
Consumer products	3%
Miscellaneous*	<1%

* includes occupation exposure, nuclear fallout, and the production of nuclear materials for nuclear power and weapons

Epidemiological data on radiation sickness has been accumulated from the study of individual cases, as well as from the study of large numbers of afflicted individuals, such as the survivors of the atomic bombing of Hiroshima and Nagasaki and the 135,000 people evacuated from close proximity to the fire at the **Chernobyl Nuclear Power Station** in 1986.

In those who survive, radiation sickness may be characterized by four phases. The initial stage occurs immediately after exposure and is characterized by nausea, vomiting, weakness, and diarrhea. This is a period of short duration, typically one or two days. It is followed by a period of apparent recovery lasting for one to three weeks. No particular symptoms appear during this time. The third stage is characterized by fever, infection, vomiting, lesions in the mouth and pharynx, abscesses, bloody diarrhea, hemorrhages, weight loss, hair loss, bleeding ulcers, and petechiae, small hemorrhagic spots on the skin. During this phase, there is a loss of appetite, nausea, weakness, and weight loss. These symptoms are due to the depletion of cells which would normally be rapidly dividing. Bone marrow depression occurs with reduced numbers of white blood cells, red blood cells, and blood platelets. Gut cells that are normally lost

are not replaced and hair follicle cells are depressed resulting in hair loss. If death does not occur during this phase, a slow recovery follows. This is the fourth phase, but recovery is frequently accompanied by long-lasting or permanent disabilities including widespread scar tissue, cataracts, and blindness.

The toxic side effects of many **cancer** chemotherapeutic agents are similar to acute radiation sickness, because both radiation and chemotherapy primarily affect rapidly dividing cells. Little effective treatment can be administered in the event of casualties occurring in enormous numbers such as in war or a major **nuclear power** plant disaster. However, in individual cases such as in accidental laboratory or industrial exposure, some may be helped by isolation placement to prevent infection, transfusions for hemorrhage, and bone marrow transplantation. *See also* Epidemiology; Nuclear weapons; Nuclear winter; Radiation exposure; Radioactive pollution; Threshold dose

Radioactive decay

Radioactive decay is the process by which an atomic nucleus undergoes a spontaneous change, emitting an **alpha particle** or **beta particle** and/or a **gamma ray**. Radioactive decay is a natural process that takes place in the air, water, and **soil** at all times. The decay of isotopes such as uranium-238, radium-226, radon-222, potassium-40, and carbon-14 produce radiation that poses an unavoidable and, probably, minimal hazard to human health. Scientists have also learned how to convert stable isotopes to radioactive forms. The radioactive decay of these isotopes has been added to the natural **background radiation** from naturally radioactive materials. *See also* Carbon; Radioactive fallout; Radioactivity

Radioactive fallout

In the 1930s, scientists found that bombarding **uranium** metal with neutrons caused the nuclei of uranium atoms to break apart, or fission. One significant feature of this reaction was that very large amounts of energy were released during **nuclear fission**. The first practical application of this discovery was the atomic bomb, developed by scientists working in the United States in the early 1940s.

The atomic bomb takes advantage of the energy released during fission to bring about massive destruction of property and human life. However, every bomb blast is also accompanied by another event known as radioactive fallout. The term radioactive fallout refers to all radioactive dust and particles that fall to the earth after a nuclear explosion. This combination of dust and particles contains hundreds of isotopes formed when a uranium nucleus fissions. Iodine-131 and yttrium-98 are only two of the many isotopes that are formed during an atomic bomb blast.

When these isotopes are formed, they come together as only very small particles. The force of the blast assures that large particles will not survive. In this form, the radioactive dust and particles may remain suspended in air for days, weeks, or months. Only when they have consolidated to form larger particles will they fall back to Earth.

Once they have reached the earth, these particles face different fates. Some isotopes formed during fission have very short half-lives. They will decay rapidly and pose little or no environmental threat. Others have longer half-lives and may remain in the **environment** for many years.

The components of radioactive fallout that cause the greatest concern are those that can take some role in plant or animal **metabolism**. For example, the element strontium is chemically similar to the element calcium. Strontium can replace calcium in many biochemical reactions. That explains why the following scenario is so troubling.

Strontium-90 released during a fission bomb blast falls to the earth, coats grass, and is eaten by cows. The cows incorporate strontium-90 into their milk, just as they do calcium. When growing children drink that milk, the strontium-90 is used to build bones and teeth, just as calcium is. Once incorporated into bones and teeth, however, the radioactive strontium continues to emit harmful radiation for many years.

The dangers of radioactive fallout are one of the major reasons that the United States and the former Soviet Union were able to agree in 1963 on a limited ban of **nuclear weapons** testing. In that agreement, both nations promised to stop nuclear weapons testing in the **atmosphere**, under water, and in outer space. *See also* Half-life; Radioactive decay; Radioactivity

Jagger, J. *The Nuclear Lion: What Every Citizen Should Know About Nuclear Power and Nuclear War.* New York: Plenum, 1991.

Radioactive pollution

Radioactive **pollution** can be defined as the release of radioactive substances or high-energy particles into the air, water, or earth as a result of human activity, either by accident or by design. The sources of such waste include: 1) nuclear weapon testing or detonation; 2) the *nuclear fuel cycle*, including the mining, separation, and production of nuclear materials for use in nuclear **power plants** or nuclear bombs; 3) accidental release of radioactive material from **nuclear power** plants. Sometimes natural sources of **radioactivity**, such as **radon** gas emitted from beneath the ground, are considered pollutants when they become a threat to human health.

Since even a small amount of **radiation exposure** can have serious (and cumulative) biological consequences, and since many radioactive wastes remain toxic for centuries, radioactive pollution is a serious environmental concern even though natural sources of radioactivity far exceed artificial ones at present.

The problem of radioactive pollution is compounded by the difficulty in assessing its effects. **Radioactive waste** may spread over a broad area quite rapidly and irregularly (from an abandoned dump into an **aquifer**, for example), and may not fully show its effects upon humans and organisms for decades in the form of **cancer** or other chronic diseases. For instance, radioactive iodine-131, while short-lived, may leave those who ingest it with long-term health problems. By the time a radioactive leak is revealed and a health survey is carried out, many of the individuals affected by the leak may have already moved from the area (or died without having been examined with the possible cause in mind). In addition, since most radioactive materials are under the jurisdiction of governmental agencies—usually in the secretive defense and military establishments—the dumping activities and accidental discharges that accompany nuclear materials production and bomb testing tend to remain concealed until governments are obligated to disclose them under public pressure.

Atmospheric pollution

Radioactive pollution that is spread through the earth's **atmosphere** is termed *fallout*. Such pollution was most common in the two decades following World War II, when the United States, the Soviet Union, and Great Britain conducted hundreds of **nuclear weapons** tests in the atmosphere. France and China did not begin testing nuclear weapons until the 1960s and continued atmospheric testing even after other nations had agreed to move their tests underground.

Three types of fallout result from nuclear detonations: local, tropospheric, and stratospheric. Local fallout is quite intense but short-lived. Tropospheric fallout (in the lower atmosphere) is deposited at a later time and covers a larger area, depending on meteorological conditions. Stratospheric fallout, which releases extremely fine particles into the upper atmosphere, may continue for years after an explosion and attain a worldwide distribution.

The two best known examples illustrating the effect of fallout contamination are the bombing of Hiroshima and **Nagasaki, Japan** in 1945, and the **Chernobyl Nuclear Power Station** disaster in April 1986. Within five years of the American bombing of Japan, as many as 225,000 people had died as a result of long-term exposure to radiation from the bomb blast, chiefly in the form of fallout.

The disaster at the Chernobyl Nuclear Power Station in Ukraine on April 26, 1986 produced a staggering release of radioactivity. In 10 days at least 36 million curies spewed across the world. The fallout contaminated approximately 1,000 square mi (2,590 sq km) of farmland and villages in the Soviet Union. Dangerous levels of radioactivity were reported in virtually every European country, and radioactive pollutants contaminated rainwater, pastures and food crops. Radiation alerts were posted in almost every country, children were kept indoors, and sales of milk, vegetables, and meat were banned in some areas. In the Soviet Union alone, 135,000 people were evacuated from their homes. In addition to the hundreds killed at the time of the explosion, scientists predict the eventual Soviet death toll from the Chernobyl accident may reach 200,000; the estimated **mortality** in western Europe may approach 40,000.

Pollution on land and in water

The major sources of radioactive pollution on land and water include: 1) the nuclear fuel cycle—the extraction, separation and refinement of materials for use in nuclear weapons and nuclear power—and 2) the day-to-day operations of nuclear power plants.

At every stage in the production of nuclear fuels, contaminants are left behind. The mining of **uranium**, for example, produces highly radioactive *tailings* which can be blown into the air, contaminate **soil**, or leach into bodies of water. The magnitude of radioactive pollution caused by the nuclear fuel cycle, especially in the United States, Great Britain, and the Soviet Union, has only recently been revealed. Through the years of the cold war, the extent of accidental discharges and intentional dumping carried out by government plants like Britain's Windscale and the United States' **Hanford Nuclear Reservation** remained largely unknown. Not until the late 1980s, for instance, was the legacy of flagrant pollution at Hanford exposed to public scrutiny. This legacy included the release of half a million curies of radioactive iodine into the air from 1944 to 1955, and the

release of millions of curies of radioactive material into the Columbia River, Washington from 1944 through at least the 1960s. In 1956, 450,000 gal (1.7 million l) of high-level waste were accidently spilled on the Hanford grounds. Through the 1950s, additional millions of gallons of waste were dumped into the ground. Residents in the area and along the river were never notified about any of the radioactive discharges that took place at Hanford.

In 1988, the **U.S. Department of Energy** reported that radioactive wastes from Hanford were contaminating some underground water supplies; Hanford was shut down a year later. At present, a farm of deteriorating storage tanks at Hanford containing approximately 57 million gal (216 million l) of radioactive and toxic waste is being monitored for leaks. Officials are not even sure what **chemicals** lie in some of these tanks. Federal officials estimate that cleaning up Hanford and the U.S. government's other weapons facilities (at Fernald, Ohio; Rocky Flats; Colorado; Savannah River, Georgia; and other locations) may cost over $200 billion.

Nuclear power plants also contribute to radioactive pollution. Spent nuclear fuel from these plants, a *high-level* waste, must be kept from human contact for hundreds or thousands of years, yet no completely reliable disposal method exists. At present, most high-level waste has simply been left in pools at power plant sites while the government seeks a location for permanent disposal. Most *low-level* waste (anything that is not spent fuel or transuranic waste) generated by nuclear power plants has been landfilled throughout the country. Three such **landfill** sites (Maxey Flats, Kentucky; West Valley, New York; and Sheffield, Illinois) have been shut down due to leakage of radioactive liquid into the ground.

Nuclear power plants also **discharge** wastes directly, as a result of malfunctions or intentional dumping. During the decade from 1979 to 1989, the **Nuclear Regulatory Commission** recorded 33,000 mishaps at power plants in the United States, 1,000 of which it classified as "particularly significant." Though the vast majority of these incidents resulted in no release of radioactive material, some accidents, such as the Three Mile Island partial meltdown and the Chernobyl explosion, have caused significant discharges of radioactivity into the **environment**. A sampling of incidents:

- the Vermont Yankee power plant, a power station with a poor safety record, was fined $30,000 for dumping 83,000 gal (314,000 l) of radioactive water into the Connecticut River in July 1976;
- the accident at Three Mile Island, Pennsylvania in 1979 released 2.5 million curies of radioactive noble gases and a small quantity of radioactive iodine into the atmosphere;
- in one of a series of 21 unreported leaks occurring up to March 1981, radioactive material from the Tsuruga nuclear power plant in Japan was dumped into Tsuruga Bay after warning alarms were shut off; operators of the plant later admitted that they intentionally dumped wastes regularly;
- in October 1982, heavy rains caused a flood at the Cofrentes nuclear power plant in Spain which released 154 gal (580 l) of radioactive waste;
- in December 1985, a power failure at the Rancho Seco, California plant resulted in a release of a small quantity of radiation into the air; in 1989 the NRC fined the facility $100,000 for violating waste disposal regulations from 1983 to 1986;
- at the Douglas Point, Canada, station in January 1986, it was discovered that **high-level radioactive waste** had been leaking from a spent-fuel "storage pond" at a rate of 16 gal (60 l) per hour.

The health effects of radioactive leaks are still debated. While the harmful effects of Chernobyl are probably beyond question, analysis of the Three Mile Island incident has not detected a long-term increase in cancer or diseases as a result of the discharge there. Studies conducted in England, however, reveal increased rates of **leukemia** in areas surrounding the nuclear plants at Hinkley Point, Dounreay, and Windscale.

Radioactive waste

Radioactive waste is the "garbage" left as a result of the use of nuclear materials by human societies. Such waste can be categorized as low-level, intermediate-level, or high-level waste. The term *transuranic waste* is also used to describe

materials consisting of elements heavier than **uranium** in the periodic table.

The term **low-level radioactive waste** usually refers to materials that contain a small amount of **radioactivity** dispersed in a large volume of material. Such materials are produced in a great variety of industrial, medical, and research procedures. A common practice is to store these materials in sealed containers until their level of radioactivity is very low and then to dispose of them by shallow burial or in other traditional **solid waste** disposal systems.

The assumption is that the level of radiation released by these wastes is too low to cause any harmful environmental effects. That assumption has been challenged by some scientists who believe that enough is not yet known about the long-term effects of radiation. They suggest that safer methods of disposal for such wastes need to be developed.

Intermediate-level wastes, as the name suggests, contain a higher level of radioactivity than low-level wastes, but a lower level than high-level wastes. These materials cannot be discharged directly into the **environment**. An important source of such wastes is the re-processing of nuclear fuels. At one time, large quantities of intermediate-level wastes were dumped into the deepest parts of the Atlantic Ocean. That practice has been discontinued and intermediate-level wastes are now being stored on land until a permanent disposal system is developed.

High-level radioactive wastes consist of materials that contain a large amount of radioactivity that will remain at dangerous levels for hundreds or even thousands of years. These materials pose the most difficult disposal problem of all since they must be completely isolated and stored for very long periods of time. The primary sources of high-level wastes are nuclear **power plants** and research and development of **nuclear weapons**.

A number of methods for the storage of high-level wastes have been suggested. Among these are burial in large chunks of concrete, encapsulation in glass or ceramic, projection of them inside rockets into outer space, and burial in the Antarctic ice sheet. Various countries around the world have developed a variety of methods for storing their high-level wastes. In Canada, such wastes have been stored in water-filled pools for more than 25 years. France, with one of the world's largest **nuclear power** establishments, has developed no permanent storage system but plans to build a large underground vault for its wastes by the early twenty-first century.

In the United States, Congress passed the Nuclear Waste Policy Act in 1982, outlining a complete program for the construction of a high-level waste repository in the early twenty-first century. In 1987, **Yucca Mountain**, Nevada, was selected as the location for that site. Current plans call for a huge vault 1,000 ft (305 m) underground as the site for long-term, high-level waste storage at this location. *See also* Nuclear fission; Nuclear Regulatory Commission (NRC); Ocean dumping; Office of Civilian Radioactive Waste Management (OCRWM); Radioactive decay; Radioactive waste management

Radioactive waste management

Radioactive waste materials are produced as by-products of research, **nuclear power** generation, and **nuclear weapons** manufacture. Radioactive waste is classified by the U.S. government into five groups: high-level, transuranic (chemical elements heavier than **uranium**), spent fuel, uranium mill **tailings**, and **low-level radioactive waste**.

The management and disposal of radioactive waste receives attention at all levels of state and local governments, but the regulations sometimes conflict or are confusing. The U.S. Congress passes relevant legislation, the **Environmental Protection Agency** (EPA) sets applicable environmental standards, and the **Nuclear Regulatory Commission** (NRC) develops regulations to implement the standards. For **high-level radioactive waste**, the **U.S. Department of Energy** (DOE) is responsible for the design, construction and operation of suitable disposal facilities. And courts have recently gotten into the act, ordering states to arrange to have necessary disposal facilities designed, constructed and operated for management of low-level wastes.

The principal federal laws related to the management and disposal of radioactive waste include the Atomic Energy Act (1954), the Uranium Mill Tailings Radiation Control Act (1978), the Low-Level Radioactive Waste Policy Act (1980), the Nuclear Waste Policy Act (1982), the Low-Level Radioactive Waste Policy Amendments Act (1985), and the Nuclear Waste Policy Amendments Act (1987). In

A map of the United States showing radioactive waste disposal site locations. (McGraw-Hill Inc. Reproduced by permission.)

addition, the Federal Facility Compliance Act (1992) forces the military to clean up its waste sites.

One of the more difficult aspects of the regulatory quagmire is the problem of dealing with waste, especially spent nuclear fuel and contaminated material such as worn-out reactor parts. Today, the official policy objective for nuclear waste is to dispose of it so that it will never do any appreciable damage to anyone, under any circumstances, for all time. However, for some radioactive waste, "for all time" is measured in thousands of years.

Although radioactive waste carries some hazard for many years, **radioactive decay** removes most of the hazard after a few hundred years. A well-designed waste storage system can be made safe for a long time, some scientists and policy-makers insist, provided that engineers ensure that **erosion**, **groundwater**, earthquakes, and other unpredictable natural or human activities do not breach safety barriers.

Disposal methods for radioactive wastes have varied. Over the past 50 years, low-level wastes have been flushed down drains, dumped into the ocean, and tossed into landfills. Uranium mill tailings have been mounded into small hills at sites throughout the western United States. Storage tanks and barrels at DOE sites hold millions of gallons of radioactive waste and toxic **chemicals**, the by-products of **plutonium** production for nuclear weapons.

Over 80% of the total volume of radioactive waste generated in the United States is considered low-level. There is now a shift away from the most common disposal method of shallow land burial. Because of public demand for disposal methods that provide the greatest safety and security, disposal methods now include above- and below-ground vaults and earth-mounded concrete bunkers.

However, the country's 17,000 laboratories, hospitals, and nuclear **power plants** that produce low-level radioactive byproducts could become *de facto* disposal sites. The federal low-level radioactive waste policy enacted in 1980 was designed to remedy the inequity of shipping all the nation's low-level radioactive waste to three states (Illinois, Kentucky, and New York) which never agreed to serve as the nation's sole disposal facilities. Its intent was to require every state to either build its own low-level repository or compact with other states to build regional facilities by 1986. The 1980

federal act was amended in 1985, when it became clear that the 1986 target would not be met, and the deadline was postponed to 1993. As of late 1992, however, few states had even determined sites for such facilities. And after 1996, the institutions generating low-level wastes will be held liable for all low-level wastes they produce.

The principal sources of high-level radioactive waste are nuclear power plants, and programs of the U. S. Department of Defense and DOE, especially those dealing with nuclear weapons. These wastes include spent fuel removed from nuclear plants, and fission products separated from military fuel that has been chemically processed to reclaim unused uranium and plutonium. In the United States, commercial nuclear power plant fuel removed from those facilities is stored on-site until a geologic repository is completed. The expected completion date for the repository is 2010.

Typically, waste fuel is stored at the power station in a pressurized **buffer** storage tube for 28 days, then the fuel rod is broken down to component parts. Irradiated fuel elements then are stored for 80 days in a water-filled pond to allow for further decay. For the nonreusable radioactive waste that remains, about 2.5%, there is no totally safe method for disposal.

Radioactive waste from one of the first nuclear bomb plants is so volatile that the clean-up problems have stymied the experts. The plant at the DOE's **Hanford Nuclear Reservation** near Richland, Washington, is the nation's largest repository of nuclear waste. There, 177 tanks contain more than 57 million gal (26 million l) of radioactive waste and toxic chemicals, byproducts of plutonium production for nuclear weapons. The DOE and Westinghouse Corporation (the contractor in charge of Hanford's clean-up) are still not sure exactly what mixture of chemicals and radioactive waste each tank contains, but a video taken inside one tank shows the liquid bubbling and roiling from chemical and nuclear reactions. Corrosive, highly radioactive liquids have eaten through Hanford's storage tanks and are being removed to computer-monitored, carbon-steel storage tanks. The clean-up at Hanford could cost as much as $57 billion. The only other country known to have had a waste problem as large as the one at Hanford is the former Soviet Union, where a nuclear waste dump exploded in the nuclear complex at Chelyabinsk in 1957, contaminating thousands of square miles of land.

As the military starts massive clean-up efforts, it has identified 17 nuclear facilities as among the worst of the more than 20,000 suspected toxic sites. For example, since the 1970s, about 77,000 barrels of low-level radioactive wastes have been stored at the **Oak Ridge, Tennessee** nuclear reservation. Today, some barrels are rusting and leaking **radioactivity**. Other identified radioactive waste sites include California's Lawrence Livermore National Laboratory and Sandia National Laboratory, Colorado's **Rocky Flats nuclear plant**, and New Mexico's Los Alamos National Laboratory. The Savannah River nuclear plant in South Carolina has been called especially dangerous. Both the **Savannah River site** and the Hanford site pose the risk of the kind of massive nuclear waste explosion that occurred at Chelyabinsk.

One new technology in development for the treatment of hazardous and radioactive waste is *in situ vitrification* (ISV), which utilizes electricity to melt contaminated material in place. This technology was developed primarily to treat radioactive waste, but it also has applications to hazardous chemical wastes. The end-result glass formed by ISV is unaffected by extremes of temperature, is not biotoxic, should remain relatively stable for one million years, and passes government tests that measure the speed of contaminant **leaching** over time. The process permits treatment of mixtures of various wastes including organic, inorganic, and radioactive. The fact that it is not necessary to excavate the waste prior to treatment is seen as a major advantage of the technology, since excavation along with **transportation** increases health risks. The technology is currently being used in the United States at Superfund sites.

Incineration is also used for disposal of low-level radioactive waste, but incomplete **combustion** can produce dioxins and other toxic ash and aerosols. Although finding a site for ash disposal is difficult, the ash is considered a better form for burial than the original waste. It is biologically and structurally more stable, and many of the compounds it contains are insoluble. The residual waste produced by incineration also is less susceptible to leaching by rain and groundwater.

Although progress is slow and the situation is often chaotic in the United States, the state of radioactive **waste management** in much of the rest of the world is even less advanced. The situation is particularly acute in Eastern Europe and the former Soviet Union, since these countries have generated huge quantities of radioactive waste. In many cases the information-gathering necessary to plan clean-up efforts has not begun or is barely underway, and most, if not all, of the actual clean-up remains. *See also* Eastern European pollution; Ocean dumping; Radiation exposure; Radiation sickness; Radioactive pollution; Waste Isolation Pilot Plant; Yucca Mountain, Nevada

Radioactivity

In 1896, the French physicist Henri Becquerel accidentally found that an ore of **uranium**, pitchblende, emits an invisible form of radiation, somewhat similar to light. The phenomenon was soon given the name *radioactivity* and materials like pitchblende were called *radioactive*.

The radiation Becquerel discovered actually consists of three distinct parts, called alpha, beta, and gamma rays. Alpha and beta rays are made up of rapidly moving particles—helium nuclei in the case of alpha rays, and electrons in the case of beta rays. Gamma rays are a form of electromagnetic radiation with very short wavelengths.

Alpha rays have relatively low energies and can be stopped by a thin sheet of paper. They are not able to penetrate the human skin and, in most circumstances, pose a relatively low health risk. Beta rays are more energetic, penetrating a short distance into human tissue, but they can be stopped by a thin sheet of **aluminum**. Gamma rays are by far the most penetrating form of radiation, permeating wood, paper, plastic, tissue, water, and other low-density materials in the **environment**. They can be stopped, however, by sheets of **lead** a few inches thick.

Radioactivity is a normal and ubiquitous part of the environment. The most important sources of natural radioactivity are rocks containing radioactive isotopes of uranium, thorium, potassium, and other elements. The most common radioactive **isotope** in air is carbon-14, formed when neutrons from cosmic ray showers react with **nitrogen** in the **atmosphere**. Humans, other animals, and plants are constantly exposed to low-level radiation emitted from these isotopes, and they do suffer to some extent from that exposure. A certain number of human health problems—cancer and genetic disorders, for example—are attributed to damage caused by natural radioactivity.

In recent years, scientists have been investigating the special health problems related to one naturally occurring radioactive isotope, radon-226. This isotope is produced when uranium decays, and since uranium occurs widely in rocks, radon-226 is also a common constituent of the environment. Radon-226 is an alpha-emitter, and though the isotope does have a long **half-life** (1,620 years), the alpha particles are not energetic enough to penetrate the skin. The substance, however, is a health risk because it is a gas that can be directly inhaled. The alpha particles come into contact with lung tissue, and some scientists now believe that radon-226 may be responsible for a certain number of cases of lung **cancer**. The isotope can be a problem when homes are constructed on land containing an unusually high concentration of uranium. Radon-226 released by the uranium can escape into the basements of homes, spreading to the rest of a house. Studies by the **Environmental Protection Agency** (EPA) have found that as many as eight million houses in the United States have levels of radon-226 that exceed the **maximum permissible concentration** recommended by experts.

Though Becquerel had discovered radiation occurring naturally in the environment, scientists immediately began asking themselves whether it was possible to convert normally stable isotopes into radioactive forms. This question became the subject of intense investigation in the 1920s and 1930s, and was finally answered in 1934 when Irène Curie and Frèdèric Joliot bombarded the stable isotope aluminum-27 with alpha particles and produced phosphorus-30, a radioactive isotope. Since the Joliot-Curie experiment, scientists have found ways to manufacture hundreds of artificially radioactive isotopes. One of the most common methods is to bombard a stable isotope with gamma rays. In many cases, the product of this reaction is a radioactive isotope of the same element.

Highly specialized techniques have recently been devised to meet specific needs. Medical workers often use radioactive isotopes with short half-lives because they can be used for diagnostic purposes without remaining in a patient's body for long periods of time. But the isotope cannot have such a short half-life that it will all but totally decay between its point of manufacture and its point of use.

One solution to this problem is the so-called "molybdenum cow." The cow is no more than a shielded container of radioactive molybdenum-99. This isotope decays with a long half-life to produce technetium-99, whose half-life is only six hours. When medical workers require technetium-99 for some diagnostic procedure, they simply "milk" the molybdenum cow to get the short-lived isotope they need.

Artificially radioactive isotopes have been widely employed in industry, research, and medicine. Their value lies in the fact that the radiation they emit allows them to be tracked through settings in which they cannot be otherwise observed. For example, a physician might want to know if a patient's thyroid is functioning normally. In such a case, the patient drinks a solution containing radioactive iodine, which concentrates in the thyroid like stable iodine. The isotope's movement through the body can be detected by a Geiger counter or some other detecting device, and the speed as well as the extent to which the isotope is taken up by the thyroid is an indication of how the organ is functioning.

Artificially radioactive isotopes can pose a hazard to the environment. The materials in which they are wrapped, the tools with which they are handled, and the clothing worn by workers may all be contaminated by the isotopes. Even after they have been used and discarded, they may continue to be radioactive. Users must find ways of disposing of these wastes without allowing the release of dangerous radiation into the environment, a relatively manageable problem. Most materials discarded by industry, medical facilities, and researchers are **low-level radioactive waste**. The amount of radiation released decreases quite rapidly, and after isolation for just a few years, the materials can be disposed of safely with other non-radioactive wastes.

The same cannot be said for the **high-level radioactive waste** produced by nuclear **power plants** and defense research and production. Consisting of radioactive isotopes, such wastes are produced during fission reactions and release dangerously large amounts of radiation for hundreds or thousands of years.

Nuclear fission was discovered accidentally in the 1930s by scientists who were trying to produce artificial radioactive isotopes. In a number of cases, they found that the reactions they used did not result in the formation of new radioactive isotopes, but in the splitting of atomic nuclei, a process that came to be known as nuclear fission.

By the early 1940s, nuclear fission was recognized as an important new source of energy. That energy source was first put to use for destructive purposes, in the construction of **nuclear weapons**. Later, scientists found ways to control the release of energy from nuclear fission in nuclear reactors.

The most serious environmental problem associated with fission reactions is that their waste products are largely long-lived radioactive isotopes. Attempts have been made to isolate these wastes by burying them underground or sinking them in the ocean. All such methods have proved so far to be unsatisfactory, however, as containers break open and their contents leak into the environment.

The United States government has been working for more than four decades to find better methods for dealing with these wastes. In 1982, Congress passed a *Nuclear Waste Policy Act*, providing for the development of one or more permanent burial sites for high-level wastes. Political and environmental pressures have stalled the implementation of the act and a decade after its passage, the nation still has no method for the safe disposal of its most dangerous radioactive wastes. *See also* Ecotoxicology; Hazardous waste; Nuclear fusion; Nuclear winter; Radiation exposure; Radiation sickness; Radioactive fallout; Radioactive pollution; Radioactive waste management

Radiocarbon dating

Radiocarbon dating is a technique for determining the age of very old objects consisting of organic (carbon-based) materials, such as wood, paper, cloth, and bone. The technique is based on the fact that both stable and radioactive isotopes of **carbon** exist. These isotopes behave almost identically in biological, chemical, and physical processes.

Carbon-12, a stable **isotope**, makes up about 99% of all carbon found in **nature**. Radioactive carbon-14 is formed in the **atmosphere** when neutrons produced in cosmic ray showers react with **nitrogen** atoms.

Despite the fact that it makes up no more than 0.08% of the earth's crust, carbon is an exceedingly important element. It occurs in all living materials and is found in many important rocks and minerals, including limestone and marble, as well as in **carbon dioxide**. Carbon moves through the atmosphere, hydrosphere, lithosphere, and **biosphere** in a series of reactions known as the **carbon cycle**. Stable and radioactive isotopes of the element take part in identical reactions in the cycle. Thus, when green plants convert carbon dioxide to carbohydrates through the process of **photosynthesis**, they use both stable carbon-12 and radioactive carbon-14 in exactly the same way. Any living material consists, therefore, of a constant ration of carbon-14 to carbon-12.

In the mid-1940s, Willard F. Libby realized that this fact could be used to date organic material. As long as that material was alive, he pointed out, it should continue to take in both carbon-12 and carbon-14 in a constant ratio. At its death, the material would no longer incorporate carbon in any form into its structure. From that point on, the amount of stable carbon-12 would remain constant. The amount of carbon-14, however, would continuously decrease as it decayed by beta **emission** to form nitrogen. Over time, the ratio of carbon-14 to carbon-12 would grow smaller and smaller. That ratio would provide an indication of the length of time since the material had ceased being alive.

Radiocarbon dating has been used to estimate the age of a wide variety of objects ranging from charcoal taken from tombs to wood found in Egyptian and Roman ships. One

of its most famous applications was in the dating of the Shroud of Turin. Some religious leaders had claimed that the Shroud was the burial cloth in which Jesus was wrapped after his crucifixion. If so, the material of which it was made would have to be nearly 2,000 years old. Radiocarbon dating of the material showed, however, that the cloth could not be more than about 700 years old.

Radiocarbon dating can be used for objects up to 30,000 years of age, but it is highly reliable only for objects less than 7,000 years old. These limits result from the fact that eventually carbon-14 has decayed to such an extent that it can no longer be detected well or, eventually, at all in a sample. For older specimens, radioisotopes with longer half-lives can be used for age determination. *See also* Half-life; Radioactive decay

Radioisotope

The term radioisotope is shorthand for radioactive **isotope**. Isotopes are forms of an element whose atoms differ from each other in the number of neutrons contained in their nuclei and, hence, in their atomic masses. Hydrogen-1, hydrogen-2, and hydrogen-3 are all isotopes of each other.

Isotopes may be stable or radioactive. That is, they may exist essentially unchanged forever (stable), or they may spontaneously emit an **alpha particle** or **beta particle** and/or a **gamma ray**, changing in the process into a new substance. Hydrogen-1 and hydrogen-2 are stable isotopes, but hydrogen-3 is radioactive.

The first naturally occurring radioisotopes were discovered in the late 1890s. Scientists found that all isotopes of the heaviest elements—uranium, radium, **radon**, thorium, and protactinium, for example—are radioactive. This discovery raised the question as to whether stable isotopes of other elements could be converted to radioactive forms.

By the 1930s, the techniques for doing so were well established, and scientists routinely produced hundreds of radioisotopes that do not occur in **nature**. As an example, when the stable isotope carbon-12 is bombarded with neutrons, it may be converted to a radioactive cousin, carbon-13. This method can be used to manufacture radioisotopes of nearly every element.

Naturally occurring radioisotopes are responsible for the existence of **background radiation**. Background radiation consists of alpha and beta particles and gamma rays emitted by these isotopes. In addition to the heavy isotopes mentioned above, the most important contributors to background radiation are carbon-14 and potassium-40.

Synthetic radioisotopes have now become ubiquitous in human society. They occur commonly in every part of **nuclear power** plant operations. They are also used extensively in the health sciences, industry, and scientific research. A single example of their medical application is **cancer** therapy. Gamma rays emitted by the radioisotope cobalt-60 have been found to be very effective in treating some forms of cancer. Other gamma-emitting radioisotopes can also be used in this procedure.

The potential for the release of radioisotopes to the **environment** is great. For example, medical wastes might very well contain radioisotopes that still emit measurable amounts of radiation. Stringent efforts are made, therefore, to isolate and store radioisotopes until their radiation has reached a safe level.

These efforts have two aspects. Some radioisotopes have short half-lives. The level of radiation they emit drops to less than 1% of the original amount in a matter of hours or days. These isotopes need only be stored in a safe place for a short time before they can be safely discarded with other solid wastes.

Other radioisotopes have half-lives of centuries or millennia. They will continue to emit harmful radiation for thousands of years. Safe disposal of such wastes may require burying them deep in the earth, a procedure that still has not been satisfactorily demonstrated. In spite of the potential environmental hazard posed by radioisotopes, they do not presently pose a serious threat to plants, animals, or humans. The best estimates place the level of radiation from artificial sources at less than five percent of that from natural sources. *See also* Half-life; Radioactive decay; Radioactive waste management; Radioactivity

Radiological Emergency Response Team

The Radiological Emergency Response Team (RERT) of the federal **Environmental Protection Agency** (EPA) responds to emergencies that involve the release of radioactive materials. The team responds to emergencies such as accidents at nuclear **power plants**, accidents involving the shipment of radioactive material, and acts of nuclear terrorism. RERT works with the EPA Superfund Program, as well as federal, state, and local agencies to develop and enforce strategic plans.

RERT is based in the EPA Office of Radiation and Indoor Air in Washington, D.C., and at two national laboratories. **Environmental monitoring** and assessment is performed by employees at the National Air and Radiation Environmental Laboratory in Montgomery, Alabama, and the Radiation and Indoor Environments National Laboratory in Las Vegas, Nevada. Approximately 75 RERT members were stationed in Washington and at the laboratories in the spring of 2002.

In an emergency, an RERT field team goes to the site where radioactive material was released. The team's duties include taking environmental measurements and doing laboratory work. In addition, RERT works with state and local authorities to protect the public from exposure to harmful radiation levels. Team equipment ranges from a mobile radiation laboratory to the personal dosimeter used to measure the radiation dose in an individual.

Radionuclides

Radionuclides are radioactive elements. **Radioactivity** can be defined as the release of **alpha and beta** particles from atoms, and/or **gamma rays** that takes place when the nuclei of certain unstable substances spontaneously disintegrate. It is during this disintegration process that they emit radiation. The two main types of radiation released during such processes are termed **ionizing**, or of sufficient strength to forcibly eject electrons from their orbit around an atoms nucleus, producing ions, and **non-ionizing**, of less strength and incapable of displacing electrons and forming ions. **Ionizing radiation** is highly significant because when it occurs within the atoms of molecules in living things, it is capable of causing biological damage such as the death of cells or the unnatural reproduction of cells. We term this unnatural reproduction of cells **cancer**.

Radionuclides occur in the **environment** both naturally and as a result of human industry. Some naturally-occurring radionuclides exist all over the earth and have been present since its formation 4.5 billion years ago. But most elements can be made artificially radioactive by bombarding them with high-energy particles such as neutrons. Each radionuclides forms and behaves in unique ways, with its own method and rate of decay. Such decay is measured by what is called **half-life**, or the time it takes for a group of atoms to decay to half of their original number.

One of the substances that occurs naturally in the earth's crust is **uranium**, a radionuclide used often as fuel to produce **nuclear power**. Uranium is the heaviest element found on earth with the exception of tiny amounts of an element called neptunium. When the German chemist Martin H. Klaproth discovered uranium in 1789, he named it in honor of the recently discovered planet Uranus. The scientific community showed little interest in uranium until 1896, when Henri Becquerel discovered radioactivity, and uranium was named as one of only two known radioactive elements of the time. In 1938, scientists discovered **nuclear fission**, a reaction that produces energy. In fact, uranium can produce energy at nearly three million times that of **coal** (1 lb of uranium can produce the same amount of energy produced by 3 million lb [1.4 million kg] of coal).

The most abundant form (**isotope**) of uranium boasts a **half-life** nearly identical to that of the earth itself. This allows scientists to use the substance's disintegration to date

other geological features of the earth by comparison. However, uranium use also has many drawbacks. Most notably, use of the substance produces nuclear waste that must be carefully transported and stored. In addition, easily obtainable supplies of uranium on Earth are limited, therefore the costs of locating and refining uranium can be extremely high.

Radium occurs as a result of uranium disintegration. Marie Curie, the first woman to win a Nobel Prize, and one of the few scientists to ever receive the Nobel prize twice, along with her husband Pierre, discovered the substance. She had followed up on Becquerel's observations on uranium's radioactive properties for her doctoral dissertation in the late 1890s. The Curies began refining pitchblende, a waste ore that was commonly found around uranium mines, known to emit radiation. The Curies first discovered the radioactive salt they named polonium, and then radium, found to be thousands of times more radioactive than any other substance discovered to date.

Radium is found in water, **soil**, plants, and food, but at low concentrations. Drinking water holds the highest potential for human exposure to radium. When humans are exposed to radium orally, they are at risk for lung, bone, brain and nasal passage tumors. Chronic exposure has led to acute **leukemia** and other complications. Radium has been classified by the **Environmental Protection Agency** (EPA) as a human **carcinogen**. Today, radium is still considered among the most radioactive metals on Earth, and requires careful attention and handling. Its use has been limited in many products, but the substance still helps treat cancers through radiation therapy and aids in some forms of research. As evidence of the validity of the EPA's finding, its discoverer, Marie Curie died at the age of 67 of leukemia, caused by her prolonged exposure to radiation.

Radon is a gas that can diffuse out of uranium (from radium) in the ground from uranium and thorium present in minerals, ores and rocks. A German physics professor named Friedrich Dorn discovered radon in 1900, after he followed the experiments of Marie Curie. He found that radium emitted a radioactive gas he termed **radium emanation**. Dorns discovery was important because it showed that an element could be transmuted from metal to gas as part of the **radioactive decay** process. The hazards of radon were not discovered until late in the twentieth century, and since that time, testing houses for the gas has become an important precaution. Radon has shown the capability of seeping into **groundwater** and contaminating public drinking supplies.

As Radon is colorless and odorless, it can prove particularly dangerous. Radon exposure occurs mostly through inhalation of the gas in indoor locations such as schools, homes, or office buildings. Chronic exposure produces serious respiratory effects, and smokers are at particular risk for lung cancer, estimated at 10–20 times the risk of nonsmokers. Although hazardous, radon has been useful in predicting earthquakes. In 1918, the discovery by a group of Chinese scientists that radon levels in groundwater rise just before earthquakes led to the prediction of several earthquakes by monitoring radon concentrations in well water. Radon has also proves useful in detecting leaks, inspecting metal welds, and measuring flow rates. However, radons high risk status as a carcinogen outweighs its beneficial uses.

Plutonium is an example of an artificial radioactive substance. It was discovered around the early 1940s during experiments on nuclear fission conducted by a number of scientists. Plutonium is used in breeder reactors when uranium undergoes nuclear fission to produce energy and occurs as a waste product of uranium. Like uranium, plutonium produces large amounts of energy and its properties were put to the test in the first **nuclear weapons** test in New Mexico in 1945.

Knowledge of the properties and risks of all radionuclides have made it necessary for people all over the world to become more aware of the inherent dangers they possess and the necessary preventative measures needed for protection. People that work in factories that process uranium or with phosphate fertilizers are at increased risk of exposure to radionuclides, as are those living in close proximity to uranium mines. Tests can measure radioactivity levels in the body and elimination of radium and radon in exhaled breath. Uranium, radon, and radium levels can be measured in the urine.

One of the greatest challenges facing scientists and policymakers throughout the world is the safe transport and disposal of the **hazardous waste** resulting from radionuclides. The subject has been steeped in controversy for many years, as no place seems safe enough to handle storage of a substance that lives for millions of years. However, scientists continue to develop new methods for storage of nuclear byproducts. In early 2001, a Los Alamos National Laboratory team announced that certain ceramic materials held up against radiation damage and could potentially offer new solutions to resist **leaching** and radiation for thousands of years.

A consortium of international agencies promotes international cooperation in managing nuclear waste, since nearly every developed country has some sort of nuclear power or weaponry project in place. Most of these countries have developed plans to safely dispose of nuclear waste early in the twenty-first century. The United States leads most countries in storage efforts, with the 1982 passage of the Nuclear Waste Policy Act. The act identified objectives for developing geologic repositories for high-level nuclear waste.

The federal government identified **Yucca Mountain** in Nevada for deep underground storage of wastes to replace

storage that now lies at commercial nuclear **power plants** and research reactor sites in 43 states. The EPA continues to develop public health and environmental standards to set safe limits for the long-term storage of highly **radioactive waste**. However, a coalition of environmental groups also continues to watch and question the agency to ensure that the radiation standard remains protective enough. Like the **Waste Isolation Pilot Plant** (WIPP) storage facility in southern New Mexico, the Yucca Mountain site will no doubt remain controversial for some time.

The EPA provides printed fact sheets on radionuclides that warn of environmental and occupational exposure to the substances and acceptable levels of contact for humans. According to the agency, uranium is present in rocks and soil and throughout the environment, and although exposure can occur through air, higher levels generally occur in food or drinking water. Chronic long-term exposure to uranium and radon has been linked to both lung and kidney diseases. The EPA is currently in the process of promulgating new drinking water standards (the first update since 1976) regarding (non-Radon) radionuclides. These standards will become effective December 8, 2003, and will affect only Community Water Systems (CWSs), or those systems that serve more than 25 residents regularly all year.

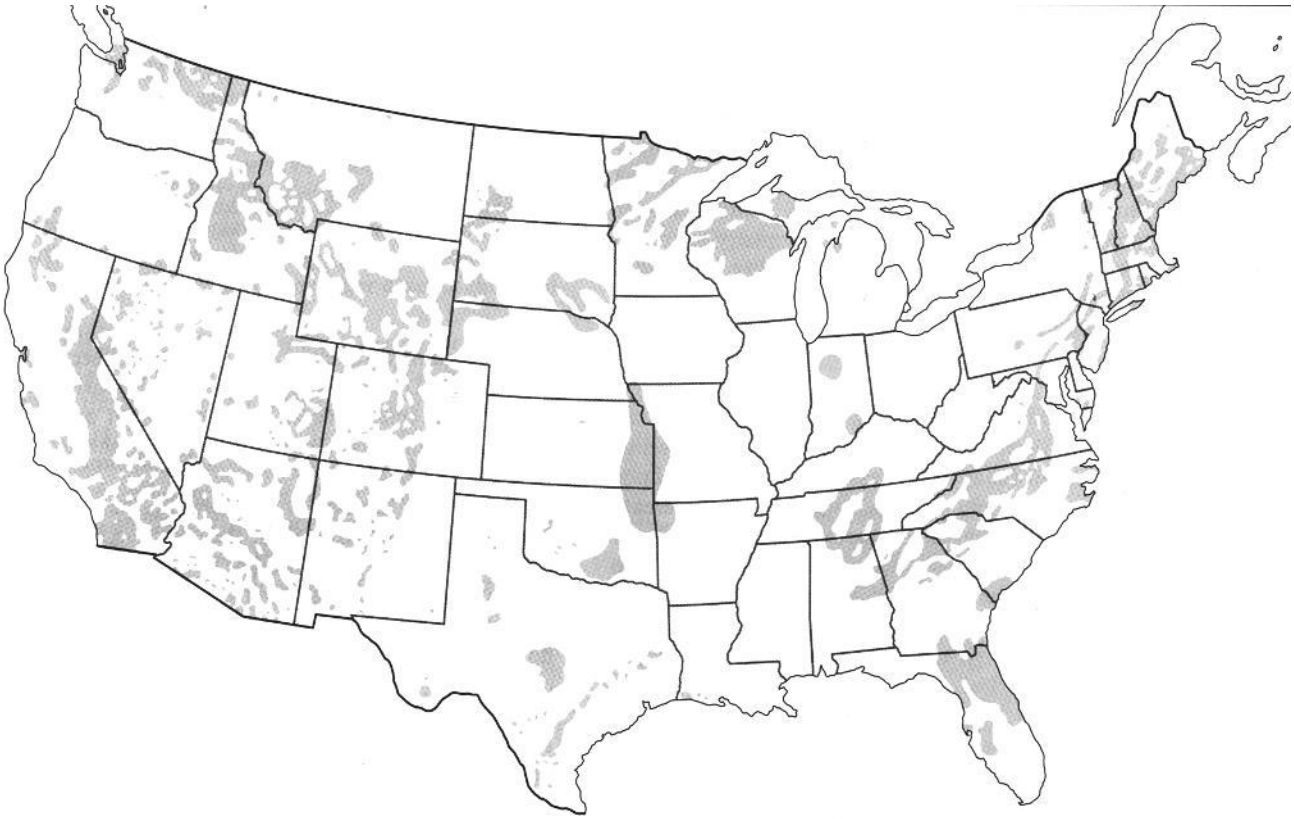
Radiotracer

A radioactive **isotope** progressing through a biological or physical system can be followed by several tracking procedures. For example, **fertilizer** containing radioactive **phosphorus** can be added to **soil**. Plants grown in this soil then take up the radioactive phosphorus just as they do non-radioactive phosphorus. If one of these plants is placed on a photographic plate, radiation from the radioactive phosphorus exposes the plate. The plant "takes its own picture," showing where the phosphorus concentrates in the plant. Radiotracers are a highly desirable research technique as they do not require the destruction of an organism for its study.



Radon

Although it has received attention as an environmental hazard only recently, radon is a naturally occurring radioactive gas that is present at low concentrations everywhere in the **environment**. Colorless and odorless, radon is a decay product of radium; radium is a decay product of the radioactive element **uranium**, which occurs naturally in the earth's crust. Radon continues to break down into products called radon progeny. Radon is measured in units called picocuries per liter (pCi/L), and it becomes a health concern when people are exposed to concentrations higher than normal background levels. Some geologic formations, such as the Reading Prong in New Jersey, are naturally very high in radon emissions.

During their normal decay process, radioactive elements emit several kinds of radiation, one of which is alpha radiation. The health effects of radon are associated with these alpha particles. These particles are too heavy to travel far and they cannot penetrate the skin, but they can enter the body through the lungs during inhalation. Studies of miners exposed to high concentrations of radon have shown an increased risk of lung **cancer**, and this is the health effect most commonly associated with radon. Background levels are usually estimated at 1 pCi/L. It is estimated that a person exposed to this concentration for 18 hours a day for five years increases their risk of developing cancer to one in 1000. At radon levels of 200 pCi/L, the increased risk of lung cancer after five years of exposure at 18 hours per day rises to 60 in 1,000. Because cancer is a disease that is slow to develop, it may take five to 50 years after exposure to radon to detect lung cancer.

In the outdoor environment, radon gas and its decay products are usually too well-dispersed to accumulate to dangerous levels. It is indoors without proper ventilation, in places such as basements and ground floors, where radon can seep from the **soil** and accumulate to dangerous concentrations. The most common methods of reducing radon buildup inside the home include installing blowers or simply opening windows. Plugging cracks and sealing floors that are in contact with soil also reduces the concentration. In the United States, environmental and public health agencies have instituted free programs to test for radon concentrations, and they also offer assistance and guidelines for reme-

The shaded areas on the map have potentially high levels of uranium in the soil and rocks. Radon levels may be high in these areas. (McGraw-Hill Inc. Reproduced by permission.)

Rails-to-Trails Conservancy

In 1985, the Rails-to-Trails Conservancy, a non-profit organization, was established to convert abandoned railroad corridors into open spaces for public use. During the nineteenth century, the railroad industry in the United States boomed as rail companies rushed to acquire land and assemble the largest rail system in the world. By 1916, over 250,000 mi (402,000) of track had been laid across the country, connecting even the most remote towns to the rest of the nation. However, during the next few decades, the **automobile** drastically changed the way Americans live and travel.

With Henry Ford's introduction of mass production techniques, the automobile became affordable for nearly everyone, and industry shifted to trucking for much of its overland **transportation**. The invention and widespread use of airplanes had a significant impact on the railroad industry as well, and people began abandoning railroad transportation.

As a result of these developments, thousands of miles of rail corridors fell into disuse. Rails-to-Trails Conservancy estimates that over 3,000 mi (4,828 km) of track are abandoned each year. Since much of the track is in the public domain, Rails-to-Trails strives to find uses for the land that will benefit the public. Thus Rails-to-Trails works with citizen groups, public agencies, railroads, and other concerned parties to, according to the organization, "build a

transcontinental trailway network that will preserve for the future our nation's spectacular railroad corridor system."

Some of the rails have been converted to trails for hiking, biking, and cross-country skiing as well as **wildlife** habitats. By providing people with information about upcoming abandonments, assisting public and private agencies in the effort to gain control of those lands, sponsoring short-term land purchases, and working with Congress and other federal and state agencies to simplify the acquisition of abandoned railways, Rails-to-Trails has mobilized a powerful grassroots movement across the country. Today there are over 11,500 mi (18,506 km) of converted rails-to-trails.

Rails-to-Trails also sponsors an annual conference and other special meetings and publishes materials related to railway **conservation**. Its quarterly newsletter, *Trailblazer*, is sent to members and keeps them aware of rails-to-trails issues. Many books and pamphlets are available through the group, as are studies such as *How to Get Involved with the Rails-to-Trails Movement* and *The Economic Benefits of Rails-to-Trails Conversions to Local Economies*. In addition, the Rails-to-Trails Conservancy provides legal support and advice to local groups seeking to convert rails to trails.

Rain forest

The world's rain forests are the richest ecosystems on Earth, containing an incredible variety of plant and animal life. These forests play an important role in maintaining the health and **biodiversity** of the planet. But rain forests throughout the world are rapidly being destroyed, threatening the survival of millions of **species** of plants and animals and disrupting **climate** and weather patterns. The rain forests of greatest concern are those located in tropical regions, particularly those found in Central and South America, and the ancient temperate rain forests along the northeastern coast of North America.

Tropical rain forests (TRFs) are amazingly rich and diverse biologically and may contain one-half to two-thirds of all species of plants and animals, though these forests cover only about 5–7% of the world's land surface. Tropical rain forests are found near the equatorial regions of Central and South America, Africa, Asia, and on Pacific Islands, with the largest remaining forest being the Amazon rain forest, which covers a third of South America.

TRFs remain warm, green, and humid throughout the year and receive at least 150 in (4 m) of rain annually, up to half of which may come from trees giving off water through the pores of their leaves in a process called **transpiration**. The tall, lush trees of the forest form a two- to three-layer closed canopy, allowing very little light to reach the ground. Although tropical forests are known for their lush, green vegetation, the **soil** stores very few nutrients. Dead and decomposing animals, trees, and leaves are quickly taken up by forest organisms, and very little is absorbed into the ground.

In 1989 *World Resources Institute* predicted that "between 1990 and 2020, species extinctions caused primarily by tropical **deforestation** may eliminate somewhere between 5–15% of the world's species...This would amount to a potential loss of 15,000 to 50,000 species per year, or 50 to 150 species per day." It is estimated that 30–80 million species of insects alone may exist in TRFs, at least 97% of which have never been identified or even discovered.

Tropical forests also provide essential winter **habitat** for many birds that breed and spend the rest of the year in the United States. Some 250 species found in the United States and Canada spend the winter in the tropics, but their population levels are decreasing alarmingly due to forest depletion.

Tropical rain forests have unique resources, many of which have yet to be utilized. Food, industrial products, and medicinal supplies are common examples. Among the many fruits, nuts, and vegetables that we use on a regular basis and which originated in tropical forests are citrus fruits, coffee, yams, nuts, chocolate, peppers, and cola. A variety of oils, lubricants, resins, dyes, and steroids are also products of the forests. Natural **rubber**, the fourth biggest agricultural export of southeast Asian nations, brings in over $3 billion a year to developing countries. The forests could also yield a sustainable supply of woods like teak, mahogany, bamboo, and others. Although only about 1% of known tropical plants have been studied for medicinal or pharmaceutical applications, these have produced 25–40% of all prescription drugs used in the United States. Some 2,000 tropical plants now being studied have shown potential as cancer-fighting agents.

Scientists studying ways to commercially utilize these forests in a sustainable, non-destructive way have determined that two to three times more money could be made from the long-term collection of such products as nuts, rubber, medicines, and food, as from cutting the trees for **logging** or cattle ranching. Perhaps the greatest value of tropical rain forests is the essential role they play in the earth's climate. By absorbing **carbon dioxide** and producing oxygen through **photosynthesis**, the forests help prevent global warming

(the **greenhouse effect**) and are important in generating oxygen for the planet. The forests help prevent droughts and **flooding**, soil **erosion** and stream **sedimentation**, maintain the **hydrologic cycle**, and keep streams and rivers flowing by absorbing rainfall and releasing moisture into the air.

Despite the worldwide outcry over deforestation, destruction is actually increasing. A 1990 study by the United Nations Food and Agriculture Organization found that tropical forests were disappearing at a rate exceeding 40 million acres (16.2 million ha) a year—an area the size of Washington state. This rate is almost twice that of the previous decade.

Timber companies in the United States and western Europe are responsible for most of this destruction, mainly through farming, cattle ranching, logging, and huge development projects. Japan, the world's largest hardwood importer, buys 40% of the timber produced, with the United States a close second. Ironically, much of the destruction of forests worldwide has been paid for by American taxpayers through such government-funded international lending and development agencies as the **World Bank**, the International Monetary Fund, and the Inter-American Development Bank, along with the United States Agency for International Development.

The release of the World Bank's new Operational Policy on Forests has been delayed since October 2001, and had not been released as of the first week in July 2002. The release has been delayed by a World Bank dispute over whether its new Forest Policy would apply to the World Bank's growing area of lending, which directly or indirectly finances logging activities. There has been widespread demand that the Forest Policy must apply to all World Bank operations that might have an impact on forests. It remains to be seen how the Operational Policy on Forests will handle this important question.

American, European, and Latin American demand for beef has contributed heavily to the conversion of rain forest to pasture land. It is estimated that one-fourth of all tropical forests destroyed each year are cut and cleared for cattle ranching. Between 1950 and 1980, two-thirds of Central America's primary forests were cut, mostly to supply the United States with beef for fast food outlets and pet food.

In Brazil and other parts of the **Amazon Basin**, cattle ranchers, plantation owners, and small landowners clear the forest by setting it on fire, which causes an estimated 23–43% increase in **carbon** dioxide levels worldwide and spreads **smoke** over millions of square miles, which interferes with air travel and causes respiratory difficulties.

Unfortunately, cleared forest that is turned into pasture land provides very poor quality soil, which can only be ranched for a few years before the land becomes infertile and has to be abandoned. Eventually **desertification** sets in, causing cattle ranchers to move on to new areas of the forest.

While huge timber and multi-national corporations have justifiably received much of the blame for the destruction of TRFs, local people also play a major role. Populations of the **Third World** gather wood for heating and cooking, and the demand brought about by their growing numbers has resulted in many deforested areas. The proliferation of coca farms, producing cocaine mainly for the American market, has also caused significant deforestation and **pollution**, as has gold prospecting in the Amazon.

The destruction of TRFs has already had devastating effects on **indigenous peoples** in tropical regions. Entire tribes, societies, and cultures have been displaced by environmental damage caused by deforestation. In Brazil fewer than 200,000 Indians remain, compared to a population of some six million about 400 years ago. Sometimes they are killed outright when they come into contact with settlers, loggers, or prospectors, either by disease or because they are shot. And those who are not killed are often herded into miserable reservations or become landless peasants working for slave labor wages.

Today, less than 5% of the world's remaining TRFs have some type of protective status, and there is often little or no enforcement of prohibitions against logging, **hunting**, and other destructive activities.

The ancient rain forests of North America are also important ecosystems, composed in large part of trees that are hundreds and even thousands of years old. Temperate rain forests (or evergreen forests) are usually composed of conifers (needle-leafed, cone-bearing plants) or broadleaf evergreen trees. They thrive in cool coastal climates with mild winters and heavy rainfall and are found along the coasts of the Pacific Northwest area of North America, southern Chile, western New Zealand, and southeast **Australia**, as well as on the lower mountain slopes of western North America, Europe, and Asia.

The rain forest of the Pacific Northwest, the largest **coniferous forest** in the world, stretches over 112,000 mi^2 (129,000 km^2) of coast from Alaska to northern California, and parts extend east into mountain valleys. The forests of the Pacific Northwest consist of several species of coniferous trees, including varieties of spruce, cedar, pine, Douglas fir, Hemlock, and Pacific yew. Broadleaf trees, such as Oregon oak, tanoak, and madrone, are also found there. Redwood tree growth extends to central California. Further south are the giant sequoias, the largest living organisms on earth, some of which are over 3,000 years old.

In some ways, the temperate rain forests of the Pacific Northwest may be the most biologically rich in the world. Although TRFs contain many more species, temperate rain

Rain forest. (Photograph by David Julian. Phototake NYC. Reproduced by permission.)

forests have far more plant matter per acre and contain the tallest and oldest trees on Earth. Over 210 species of fish and **wildlife** live in ancient forests, and a single tree can support over 100 different species of plants. One tree found in cool, moist forests is the slow-growing Pacific yew, whose bark and needles contain taxol, considered one of the most powerful anti-cancer drugs ever discovered.

Unfortunately, the **clear-cutting** of most of the ancient forests and their yew trees has caused a serious shortage of taxol. Some yew trees are unavailable for harvesting because they grow in forests protected as habitat for the endangered **northern spotted owl**. The logging of federal land under the jurisdiction of the **Bureau of Land Management** (BLM) and the U.S. **Forest Service** (USFS) has eliminated some of the last and best habitats for the Pacific yew.

The remaining ancient forest, almost all of which is now on BLM and USFS land, is being cut at a rate of 200,000 acres (81,000 ha) a year, as of 1992. At this rate it will be destroyed within less than two decades. The consequences of this destruction will include the disappearance of **rare species** dependent on this habitat, the silting of waterways and erosion of soil, and the decimation of **salmon** populations, which provide the world's richest salmon fishery, worth billions of dollars annually.

Although the timber industry claims that logging maintains jobs in the Pacific Northwest, logging **national forest** often makes no economic sense. Because of the expense of building logging roads, surveying the area to be cut, and the low price it charges for trees, the USFS often loses money on its timber sales. As a result of such "deficit" or "below cost" timber sales between 1989 and 1992, the USFS lost an average of almost $300 million a year by selling timber from national forests.

Several private **conservation** groups, such as the **Wilderness Society** and the **Sierra Club**, are working to preserve the remaining ancient forests on BLM and USFS land through federal legislation, lawsuits, and other actions. In April 1993, President Bill Clinton attended a "timber summit" in Portland, Oregon, to discuss the ancient forests, **endangered species**, and timber jobs. But the cutting of old growth forests and "below cost" timber sales have continued much as before. The Bush administration has not supported environmental issues. In 2001, President Bush triggered international outrage when he refused to agree to the Kyoto Protocol, a United Nations approved plan to preserve the **environment**.

Two of the largest remaining temperate rainforests are Alaska's 16.9 million-acre (6.8 million ha) Tongass National Forest and the Russian **Taiga**. Tongass is the last large, relatively undisturbed, temperate rain forest in the United States, stretching over 600 mi (966 km) of coast along the Alaska Panhandle. It has the highest concentration of bald eagles and grizzly bears anywhere on Earth. In addition to reducing habitat for wildlife and salmon hatching, scenic areas are being destroyed, reducing tourism and **recreation** in the area.

The huge forests in the Russian Far East and Siberia are called the Taiga. The Siberian portion is the world's largest forest. Comprising some two million mi^2 (5.1 million km^2), the Taiga is much larger than the Brazilian Amazon and would cover the entire American lower 48 states. With Russia becoming more market-oriented and in desperate need of money, some have discussed selling the logging rights to some of these forests to American, Japanese, and Korean logging companies.

Pressure from environmentalists and increasing public concern for rain forests has encouraged world leaders to consider more environmental laws. In June 1992, at the **United Nations Earth Summit** conference in Rio de Janeiro, Brazil, a set of voluntary principles to conserve the world's threatened forests were agreed upon. The document affirms the right of countries to economically exploit forests but states that this should be done "on a sustainable basis," recognizing the value of forests in absorbing carbon dioxide and slowing climate change. Initial hope that the agreement on principles might eventually be turned into a binding

international convention has evaporated, and throughout the world, forests continue to be destroyed. Some of the last remaining untouched forests are being opened up to **poaching**, logging, and other exploitation, such as the one million acre (405,000 ha) virgin Ndoke rainforest of the northern Congo Republic, a wildlife paradise full of thousand-year-old trees, along with **elephants**, leopards, gorillas, and other endangered species.

There is a small but positive sign of a much-needed change. In October 2001 Brazil suspended all trade in mahogany. The government's decision followed a two-year investigation by **Greenpeace** using ground, air, and satellite surveillance to document rampant illegal logging on Indian reservations and other protected wildlife areas. In addition, a report released in June 2002 showed that the rate of forest destruction of Brazil's Amazon jungle fell 13.4% from a five-year peak in 2000. However, the rate of destruction still deeply troubles environmentalists. *See also* Compaction; Deciduous forest; Decomposition; Migration; Old-growth forest

A rain shadow in Hawaii on the eastern side of Mount Waialeale. (McGraw-Hill Inc. Reproduced by permission.)

Rain shadow

A region of relative dryness found on the downwind side of a mountain range or other upland area. As an air mass rises over the upwind side of a mountain range, pressure drops and temperature falls. This causes the relative humidity of the air mass to rise. Eventually the moisture in the air condenses and precipitation occurs. An air mass that is now cooler and drier passes over the top of the mountain range. As it descends on the downwind side of the range, it warms again and its relative humidity is further reduced. This reduction in relative humidity not only prevents further rainfall, but also causes the air mass to absorb moisture from other sources, drying the **climate** on the downwind side. The ultimate result is lush forest on the windward side of a mountain separated by the summit from an **arid environment** on the downwind side. Examples of rain shadows include the arid areas on the eastern sides of the mountain ranges of western North America, and the Atacama **Desert** in Chile on the downwind side of the Andes Mountains.

Rainforest Action Network

Rainforest Action Network (RAN), founded in 1985, is an activist group that works to protect rain forests and their inhabitants worldwide. Its strategy includes imposing public pressure on those corporations, agencies, nations, and politicians whom the group believes are responsible for the destruction of the world's rain forests by organizing letter-writing campaigns and consumer boycotts. In addition to mobilizing consumer and environmental groups in the United States, RAN organizes and supports conservationists committed to **rain forest** protection around the world.

RAN's first direct action campaign was the boycott of Burger King. The fast-food restaurant chain was importing much of its beef from Central and South America, where large areas of forests have been turned into pastureland for cattle. RAN contends that "after sales dropped 12% during the boycott in 1987, Burger King canceled $35 million worth of beef contracts in Central America and announced that it had stopped importing rainforest beef...The formation of Rainforest Action Groups (RAGs) that staged demonstrations and held letter-writing parties in U.S. cities helped make the boycott and other campaigns a success." RAN states that there are now over 150 RAGs in North America alone.

RAN also works with human rights groups around the world, attempting to protect and save the cultures of **indigenous peoples** dependent on rain forests. The group helps support ecologically sustainable ways to use the rain forest, such as **rubber** tapping and the harvesting of such foods as nuts and fruits.

RAN urges the public to avoid buying tropical wood, such as rosewood and mahogany, and plywood made from **rain forest** timber. The group also recommends that people not buy rainforest beef, which is often found in fast-food hamburgers and processed beef products.

RAN is strongly pushing its boycott of the Japanese conglomerate Mitsubishi, which makes televisions, VCRs, fax machines, and stereos. RAN points out that "Mitsubishi has big **logging** operations in Malaysia, Borneo, Philippines, Indonesia, Chile, Canada, and Brazil...It is the world's number one importer of tropical timber." Other corporations that RAN has criticized for damaging rain forests include ARCO, Scott Paper, Coca-Cola, Texaco, and CONOCO, as well as such international agencies as the **World Bank** and the International Tropical Timber Organization (ITTO).

RAN operates an extensive media campaign targeted at companies and decision-makers who create policy on rainforests by running full-page advertisements in such major newspapers as *The New York Times* and the *Wall Street Journal*, RAN's publications include its quarterly *World Rainforest Report*; its monthly *Action Alerts*; *The Rainforest Action Guide*; and *The Rainforest Catalogue*, offering books, videos, bumper stickers, T-shirts, and other products promoting rainforest protection, as well as cosmetics and food made from rain forest plants.

Among the victories achieved by or with the help of RAN are the halting of a plan to cut down the one-million-acre (404,687-ha) La Mosquito Forest in Honduras—made famous by the movie *The Mosquito Coast*—which is essential to the cultures and livelihoods of some 35,000 indigenous people; forcing the World Bank to stop making loans to nations that destroy their rain forests; stopping **oil drilling** in the Ecuadorian Amazon by CONOCO and Du Pont; preventing the opening of a major road to take timber out of the Amazon to the Pacific Coast; and persuading Coca-Cola to donate land in Belize for a **nature** preserve.

Nevertheless, the destruction of the world's rain forests continues on an enormous scale. As RAN's director Randall Hayes points out: "Over 50 percent of the world's tropical rainforests are gone forever. Two-thirds of the southeast Asia forests have disappeared, mostly for hardwood shipped to Japan, Europe, and the U.S. And this destruction continues at a rate of 150 acres per minute, or a football field per second."

[*Lewis G. Regenstein*]

Ramsar Convention

see **Convention on Wetlands of International Importance (1971)**

Rangelands

Concentrated in 16 western states, rangelands comprise 770 million acres (311.6 million ha) and over one-third of the land base in the United States. Rangelands are vegetated predominately by shrubs, and they include **grasslands**, **tundra**, marsh, meadow, **savanna**, **desert**, and alpine communities. They are fragile ecosystems that depend on a complex interaction of plant and animal **species** with limited resources, and many range areas have been severely damaged by **overgrazing**. Currently over 300 million acres (121 million ha) within the United States alone are classified as being in need of **conservation** treatment and management. Effective range-management techniques include **soil conservation**, preservation of **wildlife habitat**, and protection of watersheds.

Raphus cucullatus

see **Dodo**

Raprenox (nitrogen scrubbing)

A recently-developed technique for removing **nitrogen oxides** from waste gases makes use of a common, nontoxic organic compound known as cyanuric **acid**, $C_3H_3N_3O_3$. When heated to temperatures of about 660°F (345°C), cya-

nuric acid decomposes to form isocyanic acid. The acid, in turn, reacts with oxides of **nitrogen** to form **carbon dioxide**, **carbon monoxide**, nitrogen, and water. The process has been given the name of *raprenox*, which comes from the expression *rap*id *re*moval of *ni*trogen *ox*ides. In tests so far, the method has worked very well with internal **combustion** engines, removing up to 99% of all nitrogen oxides from exhaust gases. Its efficiency with gases released from smokestacks has not yet been determined. *See also* Scrubbers

Rare species

A **species** that is uncommon, few in number, or not abundant. A species can be rare and not necessarily be endangered or threatened, for example, an organism found only on an island or one that is naturally low in numbers because of a restricted range. Such species are, however, usually vulnerable to any exploitation, interference, or disturbance of their habitats. Species may also be common in some areas but rare in others, such as at the edge of its natural range.

"Rare" is also a designation that the IUCN—The World Conservation Union gives to certain species "with small world populations that are not at present 'endangered' or 'vulnerable' but are at risk. These species are usually localized within restricted geographical areas or habitats or are thinly scattered over a more extensive range." Some American states have also employed this category in protective legislation.

see **Refuse-derived fuels**

Recharge zone

The area in which water enters an **aquifer**. In a recharge zone surface water or precipitation percolate through relatively porous, unconsolidated, or fractured materials, such as sand, moraine deposits, or cracked basalt, that lie over a water bearing, or aquifer, formation. In some cases recharge occurs where the water bearing formation itself encounters the ground surface and precipitation or surface water seeps directly into the aquifer. Recharge zones most often lie in topographically elevated areas where the **water table** lies at some depth. Aquifer recharge can also occur locally where streams or lakes, especially temporary ponds, are fed by precipitation and lie above an aquifer. Karst **sinkholes** also frequently serve as recharge conduits. A recharge zone can extend hundreds of square miles, or it can occupy only a small area, depending upon geology, rainfall, and surface **topography** over the aquifer. Recharge rates in an aquifer depend upon the amount of local precipitation, the ability of surface deposits to allow water to filter through, and the rate at which water moves through the aquifer. Water moves through the porous rock of an aquifer sometimes a few centimeters a day and sometimes, as in karst limestone regions, many kilometers in a day. Surface water can enter an aquifer only as fast as water within the aquifer moves away from the recharge zone.

Because recharge zones are the water intake for extensive underground reservoirs, they can easily be a source of **groundwater** contamination. Agricultural pesticides and fertilizers are especially common groundwater pollutants. Applied year after year and washed downward by rainfall and **irrigation** water, **agricultural chemicals** frequently percolate into aquifers and then spread through the local groundwater system. Equally serious are contaminants **leaching** from **solid waste** dumps. Rainwater percolating through **household waste** picks up dozens of different organic and inorganic compounds, and contamination appears to continue a long time: pollutants have recently been found leaching from waste dumps left by the Romans almost 2,000 years ago. Perhaps most serious are **petroleum** products, including **automobile** oil, which Americans dump or bury in their back yards at the rate of 240 million gal (910 million l) per year, or 4.5 million gal (18 million l) each week. On a more industrial scale, inadequately sealed toxic waste and radioactive materials contaminate extensive areas of groundwater when they are deposited near recharge zones. Because recharge occurs in a vast range of geologic conditions, all these contamination sources present real threats to groundwater quality. *See also* Hazardous waste; Radioactive waste

Reclamation

This term has been used environmentally in two distinct ways. The more historic use refers to making land productive for agriculture. The current usage refers mostly to the restoration of disturbed land to an ecologically stable condition.

The main application for agricultural purposes is the development of **irrigation**. That was the mission given in 1902 to the federal **Bureau of Reclamation** under the **U.S. Department of Agriculture**. This agency has built a total of 180 water projects in 17 western states, including the

Hoover and Glen Canyon **Dams** in Arizona, and supplies 10 trillion gal (37.8 trillion l) of water to 31 million people every year. However, this type of reclamation has led to much environmental damage and now scientists are trying to figure out how to reverse this damage. The term reclamation has also been used to describe the system of dikes and pumps in the Netherlands to allow farming of lands below sea level.

The main thrust of reclamation today is the restoration of land damaged by human activity, especially by **strip mining** for **coal**. Surface or strip mining represented a third of coal production in 1963, increasing to 60% in 1973. This increase in production led to more damage to the land and once the environmental impact was realized, the reclamation movement began. Since 1970, over two million acres (800,000 ha) of mined lands have been restored, plus 100,000 acres (40,500 ha) of abandoned mines.

However, it wasn't until 1977 that Congress finally passed the landmark legislation, the **Surface Mining Control and Reclamation Act**. Earlier attempts had failed because of the perceived threat to jobs. This act applies only to coal mining and restricts mining in prime western farmlands or where owners of surface rights object. The act requires mine operators to 1) demonstrate reclamation proficiency; 2) restore the shape of the land to the original contour and revegetate it if requested by the landowner; 3) minimize impacts on the local **watershed** and **groundwater** and prevent **acid** contamination; and 4) pay a fee on each ton of coal mined into a $4.1 billion fund to reclaim orphaned lands left by earlier mining.

Since the act was passed, it has come under fire by both industry and environmentalists, resulting in more than 50 amendments. During the Carter administration, excessive litigation caused many delays to implementing and enforcing the regulations. When Reagan was in office, 60% of the regulations were reviewed or eliminated. The **Office of Surface Mining** Reclamation and Enforcement came under attack during the first Bush administration because of its lack of performance in enforcing the legislation. During this time 6,000 mines were abandoned without reclamation and there were many exemptions from regulations.

In 1995, several amendments were proposed to minimize the duplication of state and federal regulations. A 1997 report by the Public Employees for Environmental Responsibility claimed that continued lack of enforcement led to less than one percent of the 120,000 acres (48,500 ha) strip mined in Colorado and not one acre of over 90,000 acres (36,000 ha) of stripped Indian lands being reclaimed as of 1996. During the second Bush administration, new regulations governing mining on federal lands were established in 2001, which environmentalists claimed would reinstate dated reclamation standards that led to **pollution** of land and water.

Another type of strip mining, mountaintop removal, has recently come under attack for violating the reclamation legislation. This method involves using machinery to cut off entire mountaintops, as much as 400 ft (122 m), to reach the coal underneath. The rock and earth removed from these mountaintops are dumped into nearby streams in waste piles called valley fills. Environmentalists believe many streams are being destroyed; in West Virginia alone over 1,000 mi (1600 km) of streams have been buried. These mines violate the conditions for **buffer** zone variances (no mining activities can take place within a 100-ft (30-m) buffer zone near streams, unless environmental conditions are satisfied.) Another federal court ruling in 1999 said that valley fills also violated the **Clean Water Act**. For some mine operators who claim their sites will be used for grazing or **wildlife habitat**, improper reclamation methods prevent the sites from being used for this purpose.

Reclamation clearly adds to the cost of coal. For Appalachian coal this reaches 15% of the cost per **Btu** (British Thermal Unit). The 1977 act created a level playing field where all compete under the same rules. Costs easily involve $1,000–$5,000 per acre, but this is small compared to royalties paid the landowner. In Germany, where coal seams are very thick and land values are at a premium because of heavy population pressure, great efforts are made to reclaim the land, even up to $10,000 per acre. In terms of productive farm, grazing, or timber lands, restoration after a one-time extraction of coal allows a return to **sustainable agriculture** or forestry.

Strip mining creates four landforms which the reclamation process must address: rows of **spoil** banks, final cut canyons, high walls adjacent to the final cut, and coal-haul roads. The first two are relatively easy, but the latter two require special treatment. Reshaping the land to the original contour and keeping the **soil** in place are major challenges in hilly terrain. Operators usually find it necessary to cut into the unmined hillside to make it grade into the mined land below. **Subsidence** of **overburden** could conceivably create a cliff face along the headwall if not adequately compacted. Minimizing grading during the mining process is one way to minimize the amount of land excavation and alteration.

When possible, natural looking slopes can be achieved during the mining process by mining to the prescribed safety angles, or by the cut and fill method. This is generally the most inexpensive means of reclamation. Before mining, **topography** maps should be made of existing slopes and contours so that mining can match these as close as possible.

Besides physically reshaping the land, for reclamation to succeed the essential needs of **erosion** control, **topsoil**

replacement, and nurturing and protecting young vegetation until it can survive on its own must be met. These needs are interdependent. Vegetation is crucial for erosion control, especially as the slope gradient increases; however vegetation struggles without topsoil, critical nutrients, and protection from wildlife and livestock. One additional problem, **acid mine drainage**, is eliminated by good reclamation, as the oxidizing materials which produce the acid are buried.

Coal-haul roads are very dense from the heavy vehicles traversing them. They must be ripped up and plowed for even minimal revegetation success or, less desirable, be buried under overburden. Such access roads can cause the biggest disturbance to sites since they must be designed to meet roadway standards. These roads should thus be designed to minimize grading and require careful planning.

The one most crucial element, and most expensive, is topsoil replacement. Earthwork (backfilling and grading) accounts for up to 90% of reclamation costs. Original soils provide five major benefits: 1) a seedbed with the physical properties needed for survival; 2) a **reservoir** for needed nutrients; 3) a superior medium for water **absorption** and retention; 4) a source of native seeds and plants; and 5) an **ecosystem** where the decomposer and aerator-mixer organisms can thrive. The absence of even one of these categories often dooms reclamation efforts.

The more one studies this problem, the more important the topsoil becomes; truly it is one of the earth's most vital resources. Loose overburden is sometimes so coarse and lacking in nutrients that it can support little plant cover. A quick buildup of **biomass** is critical for erosion control, but without the topsoil to sustain both plant productivity and the **microorganisms** needed to decompose the dead biomass, any ground cover is soon lost, exposing the soil to increasingly higher erosion rates.

Some areas, such as flat lowlands, can revegetate with or without human aid. But for many lands, especially those with large fractures of rock and air voids, reclamation is practically an all or nothing venture, with little tolerance for halfway measures. Indeed, in conditions where most of the negative impacts are retained within the site, reclamation may easily worsen conditions by removing the barriers to **runoff** and **sediment**.

Stabilization of the site may also be needed to complete the mining and reclamation process. Methods include extensive grading, slope alteration, hazard removal, and soil stabilization. The latter method increases the load **carrying capacity** of soils and can be achieved by using reinforced earth or a chemical treatment. The ability to handle runoff and precipitation is improved. Runoff can also be reduced by planting vegetation on top of the slope or cut.

Much of what is needed for effective reclamation is known. What has been missing has been the will to do it and the legal clout for enforcement. A new approach holds promise to increase this willingness to reclaim the land, which is based on the emerging field of eco-asset management. Ecological resources such as forests and **wetlands** are developed and treated as financial assets to their owner. This market-based approach results in higher quality reclamation, an increase in the number of sites reclaimed, and economic benefits to property owners and other participants. Hopefully, such an approach will help persuade the mining industry that reclamation is an investment in the future. *See also* Mine spoil waste; Restoration ecology

Record of Decision

A Record of Decision (ROD) is a public document that explains which remedial alternatives will be used to clean up a Superfund site. A Superfund site is a site listed on the **National Priorities List** (NPL), which identifies sites in the United States that pose the greatest long term threat to human health and the **environment**. Placement on the NPL means that clean up of the site must follow the requirements of the **Comprehensive Environmental Response, Compensation, and Liability Act**, which outlines the process for completing site clean up.

The first step in the process is to conduct a Remedial Investigation and Feasibility Study (RI/FS). During the RI, data are collected to characterize site conditions, determine the nature of the wastes, assess risk to human health and the environment, and conduct treatability studies to evaluate the potential performance and cost of treatment technologies being considered. The FS is the mechanism used to develop, screen and evaluate alternative remedial actions. A result of the RI/FS is the development of the Proposed Plan, which is the identification of a recommended remedy. The preferred remedy is one that will be effective over both the short and long-term, reduce toxicity, mobility and/or volume of contamination, be technically and economically feasible to implement, and be acceptable to the state and the community. After a period for public comment on the RI/FS and the Proposed Plan, the ROD is prepared. The ROD has three basic components: (1) the Declaration, which is an abstract and data certification sheet for the key information in the ROD and is the formal authorizing signature page; (2) the Decision Summary, which provides an overview of site characteristics, alternatives evaluated, and the analysis of those options; it also identifies the selected remedy and explains how the remedy fulfills statutory and regulatory requirements; and (3) the Responsiveness Summary, which presents stakeholder concerns that were obtained during the public comment period about the site and preferences regarding the remedial alternatives. The Summary also explains how those concerns were addressed and how the preferences were factored into the remedy selection process.

Recreation

The term recreation comes from the Latin word *recreatio*, referring to refreshment, restoration, or recovery. The modern notion of recreation is complex, and many definitions have been suggested to capture its meaning. In general, the term recreation carries the idea of purpose, usually restoration of the body, mind, or spirit. Modern definitions of recreation often include the following elements: 1) it is an activity rather than idleness or rest, 2) the choice of activity or involvement is voluntary, 3) recreation is prompted by internal motivation to achieve personal satisfaction, and 4) whether an activity is recreation is dependent on the individual's feelings or attitudes about the activity.

The terms "leisure" and "play" are often confused with recreation. Recreation is one kind of leisure, but only part of the expressive activity is leisure. Leisure may also include non-recreational pursuits such as religion, education, or community service. Although play and recreation overlap, play is not so much an activity as a form of behavior, characterized by make-believe, **competition**, or exploration. Moreover, whereas recreation is usually thought of as a purposeful and constructive activity, play may not be goal-oriented and in some cases may be negative and self-destructive.

The benefits of recreation include producing feelings of relaxation or excitement and enhancing self-reliance, mental health, and life-satisfaction. Societal benefits also result from recreation. Recreation can contribute to improved public health, increased community involvement, civic pride, and social unity. It may strengthen family structures, decrease crime, and enhance **rehabilitation** of individuals. Outdoor recreation promotes interest in protecting our **environment** and has played an important educational role. However, recreational activities have also damaged the environment. Edward Abbey, among others, have decried the tendency of *industrial tourism* to destroy wild areas and animal habitats. For example, some cite the damming of wild rivers to create lakes for boating and skiing or defacing mountain sides for ski runs and ski lifts as putting human recreation over environment.

Recreation is big business, creating jobs and economic vitality. In 2001 American consumers spent $100 billion on recreation and leisure activities. Much of these expenditures are for wildlife-related recreation. In 2001, more than 80 million Americans age 16 or older enjoyed some sort of recreation related to **wildlife** like fishing, **hunting**, bird-watching, or wildlife photography. More than 13 million

adults hunted in 2001, with overall hunting participation dropping about 7% from 1996 to 2001. Wildlife watching remained a popular outdoor activity and more than 66 milion people age 16 or older fed, photographed, or observed wildlife in 2001, spending some $40 billion on their wildlife activities.

More adults participate in walking for pleasure than any other recreational activity. Driving for pleasure, sightseeing, picnicking, and swimming are also among top recreational activities. Canoeing has been the fastest growing activity over the past 30 years.

Outdoor recreation also stimulates tourism. In 2001, almost 300 million recreation visits were made to our national parks. The United States has more than 778 million acres (314 million ha) of publicly-owned recreation lands, more than any other nation. Over one-third of the contiguous United States is public recreation land; however, these lands are not evenly distributed. Most of these lands are in the sparsely populated western states. There are 8,373 acres (3,391 ha) of public recreation lands per 1,000 people in the West, whereas there is only 294 acres (119 ha) per 1,000 people in the northeastern states. Almost 91% of the public lands area is administered by the federal government; 8% by states, 0.7% by counties, and 0.4% by municipalities. However, when number of sites, rather than acres, is considered, the recreation supply picture changes considerably. Almost 62% of all recreation sites are municipal, whereas only 1.6% of the sites are federal.

The private sector is also a major recreation supplier, particularly for certain activities. For example, there are more than 10,000 private campgrounds, 600 ski resorts, and 4,789 privately-owned **golf courses** in the United States.

Several important trends will affect the supply and demand of future recreation opportunities in the United States. Increasing populations, increasing ethnic diversity, the aging of the population, changes in leisure time, disposable income, and mobility will affect the demand for recreation. The loss of open spaces; **pollution** of our lakes, rivers, and coastlines; increasingly limited access to private lands; and increasing liability concerns will make the task of meeting future demand for recreation more difficult.

Recyclables

Recyclables are products or materials that can be separated from the **waste stream** and used again in place of raw materials. Since colonial times, Americans have recycled a host of materials, ranging from corn husks used for mattress stuffing to old clothes used for quilts. Today, household recyclables include newspapers, mixed waste paper, glass, tin, **aluminum**, steel, **copper**, **plastics**, batteries, yard debris, wood, and used oil. Commercial recyclables include scrap metals, concrete, plastics, corrugated cardboard, and other nonferrous scrap material. The list of recyclables will likely expand as technology meets a growing demand for more **recycling** in response to increased consumer awareness and waste disposal costs, dwindling **landfill** space, and more stringent **waste management** regulations. The **Environmental Protection Agency** (EPA) has emphasized the importance of diverting recyclables from the waste stream by endorsing integrated waste management, in which **municipal solid waste** is managed according to a hierarchy of source reduction, recycling, **solid waste incineration**, and landfilling.

Programs to divert household recyclables from the waste stream are typically developed and implemented at the local or community level, while commercial recyclables are usually collected by private industry. Collection and preparation methods vary among recycling programs. Some communities have implemented curbside collection programs that require households to separate recyclables from their waste and sort them into segregated containers. Other curbside collection programs pick up recyclables separated from **household waste** but commingled together. Still other communities are responsible for picking out recyclables mixed in the waste stream. In some municipalities, recyclables are sorted and prepared for processing or market at a Materials Recovery Facility (MRF). Most MRFs rely on workers to hand-sort recyclables, though some also use sorting equipment, including magnets for removing metals and blowers for sorting plastics. Plastics are also hand-sorted according to resins identified by a voluntary coding system consisting of a triangular arrow stamp with a number in the center and letters underneath that identify the seven major types of plastic resins used in containers. Other equipment exists for size reduction (shredding or grinding), weighing, and baling recyclables.

Increasing both the type and quantity of recyclables are goals of many states. In 1999, recycling (including **composting**) diverted 64 million tons of material away from landfills and incinerators. That's nearly double the amount diverted in 1990 of 34 million tons. Batteries had the highest recovery rate of any recyclable; almost 97% of all batteries were recycled. Slightly more than 41% of all paper and paperboard products were recycled and almost 40% of all plastic drink containers made their way to recycling centers, a major improvement over the last decade or so. An estimated 27% of glass was recovered from the waste stream. Approximately 54% of aluminum packaging was recovered for recycling. Recyclables also exist in the form of durable goods, which are products that have a lifetime of over three years. These are usually bulky items, such as major appliances, which are not mixed with the rest of the waste stream. Ferrous metals can be recycled from refrigerators, washing machines, and other major appliances, known as "white goods."

Recyclables are commodities, and markets for these commodities fluctuate dramatically. The dynamic nature of markets is a key factor in whether a recyclable is actually recycled instead of being disposed in a landfill or combusted in an incinerator. Municipalities involved in recycling programs must deal with rapid shifts in the market for recyclables. For example, the demand for a particular recyclable may drop, reducing the price and forcing the municipality to pay for the material to be taken away for recycling or disposal. Consequently, recycling must compete with raw material markets, as well as waste disposal methods.

An additional advantage of recycling is that it helps reduce greenhouse gas emissions. These emissions can impact the earth's **climate**. In 1996, it was estimated that recycling of **solid waste** in the United States alone may have prevented the release of 33 million tons of **carbon** into the air, about the same amount as emitted by 25 million cars in one year. *See also* Garbage; Green packaging; Municipal solid waste; Solid waste incineration; Waste reduction

Recycling

Recycling waste is not a new idea. Throughout history, people have disposed **garbage** in myriad ways. They fed household garbage to domestic animals. Scavengers gleaned the **waste stream** for usable items that could be fixed, then sold or traded for other goods and services. Homemakers mended clothing, and children grew up in hand-me-downs. Durable goods were just that; goods that could be reused until their durability wore out. These practices were not due to a desire to reduce the waste stream, but rather a need to produce products from all available resources. Modern society has moved away from such straightforward recycling practices, choosing instead to toss out the old and buy new goods. This throwaway society now faces a trash crisis.

The volume of **solid waste** generated in the United States has continued to increase, along with the cost of building landfills and **incineration** facilities. Recycling some of this material into new uses saves existing **landfill** space, conserves energy and **natural resources**, reduces **pollution**, and saves tax money. Recycling can provide new jobs, create new industries, and contribute to the increase in the GNP. Instead of referring to what people discard every day as garbage, advocates of recycling emphasize the need to refer to waste products as Post Consumer Materials (PCMs) and consider them renewable resources for various manufacturing processes.

The challenge of collecting adequate volumes of recyclable materials in a form ready for manufacturing into new products is a formidable task. Unlike raw materials that are extracted from the earth or manufactured in a lab, PCMs are mixed materials, and are sometimes contaminated with toxic and non-toxic residue. PCMs must be cleaned and source-separated at the individual household and business level. Once the materials are made available at the point of generation, they must be collected and transported to a collection site, usually referred to as a Materials Recycling Facility (MRF). At this location, materials are processed to make **transportation** easier and increase their value. Glass is separated by color, **plastics** are pelletized, and paper is baled. Other materials may be cleaned and reduced in volume, depending on the equipment available. The exceptions to this rule are single materials collected and transported directly to the point of use, such as newspaper collected at a drop off site and transported to a local insulation manufacturer. The existence of an MRF enhances the recycling process because it allows large volumes of materials to be amassed at a single location, making marketing of PCMs

more profitable. If manufacturers know that there are adequate volumes of high-quality raw material consistently available, they are more likely to agree to long-term purchasing contracts.

Manufacturers are being encouraged to retrofit, or retool, their manufacturing processes in order to use PCMs instead of raw materials. Many glass manufacturers now use cullet (cut glass) instead of silica and sand to make new glass containers, and some paper manufacturers have installed deinking equipment in order to manufacture paper from used newsprint instead of wood pulp. Once the initial expense of equipment change has been absorbed, such changes can reduce costs. But these are long-term investments on the part of manufacturers, and they must be ensured that recycling is a long-term commitment on the part of consumers and communities.

Recycling begins with people, and the biggest challenge for recycling lies in educating and motivating the public upon whom successful **source separation** depends. Except in rare circumstances recycling is a voluntary act, so the attitudes, knowledge, and feelings of the participants are the key to sustained recycling behavior. It has been found that people will change their behavior to protect the health of their families, the value of their property, and their own self-image, and recycling has often been justified in these terms. Once the rationale to begin recycling has been shared with community residents, a program for making recycling convenient and inexpensive must be institutionalized.

Curbside recycling is currently the most desirable recycling option, primarily because of its convenience. BioCycle Magazine reported in April of 1999 only nine states with fewer than 10 curbside recycling programs. These are usually commingled, or mixed, systems. Residents clean and prepare glass, cans, paper, and plastic, before putting them together in a container and placing them at the curb. Most waste haulers pick up the **recyclables** on the same day as the rest of the waste, separating them into bins on the truck right at the curb. In more rural areas, where homes are too far apart, recycling often takes place at a drop off center. This is usually a tractor trailer with separate bins, which is hauled directly to an MRF when it is full and replaced by an empty trailer. Research has shown that the best system is one where curbside recycling is offered, but a drop-off site is also available as a backup in case residents miss their recycling day. In some communities there is a weekly or monthly drop-off. Trucks from different industries use a convenient parking lot and residents are encouraged to bring their recyclables to company representatives. Some communities also have buy-back centers where residents can sell PCMs to a broker who in turn sells the material to manufacturers.

Many towns now have curbside recycling programs with trucks picking up recyclables on a weekly basis. (Photograph by Robert J. Huffman. Field Mark Publications. Reproduced by permission.)

In addition to residential recycling there is office or business recycling. Office paper recycling programs are usually set up so office workers separate the paper at their desks. The paper is taken regularly to a location where it is either baled or picked up loose and transported to a manufacturing plant. Offices that generate a large amount of white office paper can collect and market the paper directly to paper manufacturers. Smaller offices can cooperate with other businesses, contracting with paper manufacturers to pick up paper at a central location. Another example of business recycling is the recycling of corrugated cardboard by groceries and clothing stores. These businesses have been breaking down boxes and baling them on site for pickup by collection trucks. **Dry cleaning** establishments are currently taking back hangers and plastic bags from their customers for recycling. Businesses of many kinds have begun to realize that positive publicity can be achieved through their recycling efforts, and they have been increasingly inclined to participate.

One of the biggest challenges to recycling in the future is market development. For communities near to cities that have major manufacturers taking PCMs, marketing is not a problem. For smaller more rural communities, however, different strategies must be developed. In some cases a well

run MRF that brokers recycled materials is adequate. In other cases, it may be necessary to search for local markets to utilize PCMs, such as the use of newspaper as animal bedding. Newspaper collected and processed within the community can be sold to local farmers at a lower cost less than straw or sawdust. Another approach is encouraging a niche industry to locate nearby, such as a small insulation contractor who is promised all the post-consumer newsprint from the community. Ultimately, recycling will not be successful unless consumers buy products made from PCMs. Products made from these materials are becoming easier to find, and they are more clearly marked than in the past, though some green or earth-friendly product labeling has been controversial. Recycling advocates have argued that such labeling should not only say that the product is made from recycled material, it should also note what percentage of the material is post consumer waste, as opposed to manufacturing waste.

Many states are encouraging recycling through legislation. According to the Container Recycling Institute in 1999 10 states had bottle bills requiring stores to take back beer and soft drink bottles and cans, giving consumers a refund. Certain states have banned all compostable materials from landfills in order to force **composting**. In some states, daily newspapers are required to use a certain percentage of recycled paper in order to publish. These and other legislative steps have enhanced the recycling movement nationwide. States with the highest recycling rate of 40% or higher include Maine, Minnesota, New York, South Carolina, South Dakota, and Virginia according to a report in BioCycle magazine in 1999. Alaska, Montana, and Wyoming have the lowest recycle rate of 9% or less according to the report. The majority of states (40) recycle between 10 and 39% of materials. No data was available for Idaho.

According the **Environmental Protection Agency** (EPA) in 2002, U.S. consumers recycle approximately 28% of all waste. The highest recycle rate is for steel packaging, with 57% being recycled. **Aluminum** drinking cans are recycled at a rate of 55%, compared to 40% of plastic soft drink bottles. The paper recycling rate is 42%, and 52% of appliances meet with the recycler. The EPA sponsors a free voluntary program to all U.S. organizations, called WasteWise, to encourage and track the results of corporate recycling programs.

The growing tonnage of computers, computer monitors, and television sets that overpower municipal landfills is an increasing problem that demands resolution. An estimated 70% of **heavy metals** found in third millennium landfills comes from digital hardware. Eight pounds (3.6 kg) of **lead** are contained in a single cathode ray tube (CRT) monitor, contributing to the threats of lead contamination. In May of 2002 the EPA proposed a recycling program to control this high-tech waste, including a provision to classify CRT computer monitors as reusable waste products. The necessity for these measures is evident in consideration of the 500 million computers in use worldwide, which contain an estimated 1.58 billion lb (716 million kg) of lead and 632,000 lb (287,000 kg) of **mercury**. According to EPA estimates the number of discarded computers between 2002 and 2007 might reach 250 million units in the United States alone.

Equally critical is the problem of **battery recycling**. Growing concerns over poor battery recycling practices by consumers are well founded because they are classified as toxic waste, with mercury and lead contamination the most serious problems caused by improper battery disposal. Yet rarely are batteries disposed of accordingly. Most nonrechargeable batteries are tossed in the trash where they end up in the landfills. The use of rechargeable batteries offers a very effective solution to alleviate much of this problem, because each rechargeable battery has a life cycle equal to hundreds of nonrechargeable batteries; some rechargeables have a life cycle of 1,000 recharges. Because of poor disposal practices, every rechargeable battery protects the landfill from potential contamination by hundreds of batteries.

The **National Recycling Coalition** is a nonprofit organization that provides leadership and coordination at the national level, sponsoring events, scholarships, and educational programs to encourage effective recycling practices. *See also* Container deposit legislation; Municipal solid waste; Solid waste recycling and recovery; Solid waste volume reduction; Transfer station; Waste management; Waste reduction

Red tide

Red tide is the common name for phenomenon created when toxic algal blooms turn seawater red, killing marine life and making water unsuitable for human or animal use.

Red tides are caused by several **species** of dinoflagellates and diatoms, microscopic unicellular **phytoplankton** that live in cold and warm seas. A red pigment, called peridinin, which collects light during **photosynthesis**, colors the water red when large numbers of the **plankton** populate an area.

Red tides are a danger because the **toxins** released by large numbers of these plankton can paralyze fish and bioaccumulate in the tissues of shellfish and filter-feeding mollusks. Predators of the shellfish, including humans, consume the toxins causing paralysis and death.

Species of dinoflagellates that cause red tides generally belong to the "red tide genera," *Gymnodinium* and *Gonyaulax*. Though several are known to cause red tides, a single red tide is nearly always tied to a specific species. This may be the result of three factors. First, the conditions responsible for the bloom may also cause the red tide species to reproduce more rapidly than other phytoplankton, thus outcompeting them for available nutrients. Second, the toxins excreted may prevent the growth of other species. Or, behavioral differences may give them competitive advantages.

Red tides have occurred periodically through recorded history in seas around the world. The Red Sea is thought to have been named for algal blooms back in biblical times. However, in recent decades red tides have been more frequent in areas where algal blooms have never been a problem.

The coast of Chile has reported red tides since the beginning of the nineteenth century, and the Peruvian coast has recorded red tides, which they named *aguajes*, since 1828. They appear more frequently in the summer months when the water becomes warmer, and they also seem to be associated with the **El Niño** current. Coastal up-welling events are also known to be essential for the occurrence of *Gonyaulax tamarensis* blooms in the Gulf of Maine.

Red tides have been plaguing the east and west coasts of Florida on a nearly annual basis since at least 1947. Blooms on the west Florida shelf are initiated by the Loop Current, an annual intrusion of oceanic waters into the Gulf of Mexico. Here, the toxic dinoflagellate *Gymnodinium breve* produces rather predictable blooms. The red tide is transported inshore by winds, tides, and other currents where it may be sustained if adequate nutrients are available.

In 1987 and 1988, red tide spread northward from the Gulf Coast of Florida as far as North Carolina, where it caused a loss of $25 million to the shellfish industry due to brevetoxin contamination. This was the first time that *G. breve* blooms were reported so far north, and it raises the question of whether blooms will occur annually in this region. Also during the 1987–88 blooms, 700 bottlenose **dolphins** washed ashore along the United States Atlantic coast. Red tides commonly occur along the northwest coast of British Columbia, Canada, and as far north as Alaska and along the Russian coast of the Bering Sea.

Researchers blame the recent spread of red tides and the occurrence of algal blooms, which ordinarily occur in harmless low concentrations, on the increasing amount of coastal **water pollution**. Sewage and agricultural **runoff** increase concentrations of nutrients, such as **nitrogen** and **phosphorus**, in coastal waters. This increase in nutrients may create favorable conditions for the growth of red tide organisms.

In April 1992, two fishermen suffered paralytic shellfish **poisoning** (PSP) within several minutes of eating a few butter clams from Kingcome Inlet, British Columbia. In August 1992, saxitoxin, another dinoflagellate toxin associated with PSP, was found in the digestive systems of dungeness crabs caught in Alaskan waters. On Prince Edward Island, Canada, in 1987, three people died and more than 100 others became ill from domoic acid-contaminated mussels. Some of those who became ill from this toxin developed amnesic shellfish poisoning, which still causes short-term memory loss.

It is difficult to accurately predict when and where red tides may occur, and how seriously they will contaminate shellfish. Monitoring levels of toxins in shellfish meat and population sizes of the dinoflagellates is important in preventing widespread poisoning of humans. Any detectable level of brevetoxin in 3.5 oz (100 g) of shellfish meat is potentially harmful to humans. The U.S. **Food and Drug Administration** (FDA) does not inspect shellfish growing areas regularly, but relies on state agencies to monitor toxin levels. In selected states, surveillance programs have been established that randomly examine shellfish that have been harvested in natural shellfish beds. Florida is the only state that has a constant monitoring and research program for both shellfish poisoning and dinoflagellate blooms that cause poisoning. Monitoring for shellfish poisoning is costly, but the expense may increase if red tides become more frequent due to deteriorating coastal **water quality**. In April and May of 1996, 158 **manatees** in southwest Florida died from an unusual type of red tide. In China from 1997 until 1999, there were 45 red tides which wiped out 75% of the entire stock of Hong Kong's fish farms. This was an estimated $240 million loss to Hong Kong's ecomonic system. *See also* Agricultural pollution; Bioaccumulation; Competition; Marine pollution; Sewage treatment

Redwoods

There are three genera of redwood trees, each with a single **species**. The native range of the coast redwood (*Sequoia sempervirens*) is a narrow 450-mi (725-km) strip along the Pacific Ocean from central California to southern Oregon. The giant sequoia (*Sequoiadendron giganteum*) is restricted to about 75 groves scattered over a 260-mi (418-km) belt, nowhere more than 15 mi (24 km) wide, extending along the west slope of the Sierra Nevadas in central California. The third species, dawn redwood (*Metasequoia glyptostroboides*), was described first from a fossil and was presumed to be extinct. However, in 1946 live trees were discovered in a remote region of China. Since then, seeds have been brought to North America, and this species is now found in many communities as an ornamental planting. Unlike the coast redwoods and giant sequoias, dawn redwoods are deciduous.

Redwoods are named for the color of their heartwood and bark. The thick bark protects the trees from fires which occur naturally throughout their ranges. Their wood has a high tannin content which makes it resistant to **fungi** and insects, making redwood a particularly desirable building material. This demand for lumber was responsible for most of the destruction of the original redwood forests in North America. In 1918, the **Save-the-Redwoods League** was formed to save redwoods from destruction and to establish redwood parks. This organization has purchased and protected over 280,000 acres (113,400 ha) of redwood forests and was instrumental in the establishment of the Redwoods **National Park**. The term *Sequoia* used in the generic names of these species, and in the common name giant sequoia, honors the Cherokee Chief Sequoyah who developed an alphabet for the Cherokee language.

Coast redwoods. (Photograph by Jack Dermid. Photo Researchers Inc. Reproduced by permission.)

Coast redwoods

Coast redwoods are the tallest and one of the longest living tree species. Average mature trees are typically 200–240 ft (61–73 m) tall, although some trees exceed 360 ft (109 m). The world's tallest known tree is a coast redwood that stands 368 ft (112 m) tall on the banks of Redwood Creak in Redwood National Park. In some areas coast redwoods can live for more than 2,000 years. They are evergreen, with delicate foliage consisting of narrow needles 0.5–0.75 in (1.3–2 cm) long, growing flat along their stems and forming a feathery spray.

Coast redwoods are prolific. Their cones are about an inch long and contain from 30 to 100 seeds. They produce seeds almost every year with maximum seed production oc-

curring between the ages of 20–250 years old. They also have an advantage over other species in that new trees can sprout from the roots of damaged or fallen trees.

Unlike the other two species of redwoods, coastal redwoods cannot tolerate freezing temperatures. They thrive in areas below 2,000 ft (607 m), with summer fog, abundant winter rainfall, and moderate temperatures. Although coast redwoods are often found in mixed evergreen forest communities, they can form impressive pure stands, especially on flat, riparian areas with rich soils.

Giant sequoia

The giant sequoia, although not as tall as the coast redwood, is a larger and more long-lived species. Giant sequoias can attain a diameter of 35 ft (10.6 m); whereas the largest Coast redwood has a 22-ft (6.7-m) diameter. The largest tree species by volume, giant sequoias the trees through which roads were built and rangers' residences hollowed out. The most massive specimen, the General Sherman tree, located in Sequoia National Park, has a bole volume of 52,500 ft^3 (1,575 m^3)

The oldest giant sequoia is 3,600 years old, compared with 2,200 years old for the oldest coast redwood. This makes the giant sequoia the second oldest living thing on earth (the bristlecone pine is the most long-lived).

Giant sequoias can be found between elevations of 5,000 and 8,000 ft (1,517 and 2,427 m), growing best on mesic sites (such as bottomlands) with deep, well-drained sandy loam soil. Unlike coast redwoods, mature trees of this species cannot sprout from the roots, stumps, or trunks of injured or fallen trees (young trees can produce stump sprouts subsequent to injury). It is paradoxical that one of the largest living organisms is produced by one of the smallest seeds. Three thousand seeds would weigh only an ounce. Typically, cones bearing fertile seeds are not produced until the tree is 150–200 years old. The cones are egg-shaped and 2.0–3.5 in (5–9 cm) in length. Once cones develop they may continue to grow without releasing the seeds for another 20 years. A typical mature tree may produce 1,500 cones each year, and because they are not dropped annually, a tree may have 30,000 cones at one time, each with about 200 seeds. Two species of animals, a wood-boring beetle (*Phymatodes nitidus*) and the chickaree or Douglas squirrel (*Tamiasciurus douglasii*), play important roles in dislodging the seed from the cones. Fire is also important in seed release as the heat drys the cones. Fire has the added advantage of also preparing a seed bed favorable for germination. The light seeds are well-adapted for wind dispersal, often travelling up to a quarter mile away from the source tree.

Like the other redwoods, the wood of the giant sequoia is extremely durable. Because of this durability and the ornate designs in the wood, this species was harvested extensively. One tree can produce up to 600,000 board feet of lumber, enough to fill 280 railroad freight cars or build 150 five-room houses. Unfortunately, because of the enormous size of the trees and the brittle nature of the wood, when a tree was felled, as much as half would be wasted because of splintering and splitting. Now that virtually all giant trees have been protected from **logging**, the greatest threats from humans are **soil compaction** around their bases and the elimination of fire which allows fuels to accumulate, thereby increasing the chances of deadly crown fires. Toppling over is the most common natural cause of death for mature giant sequoia trees. Weakening of the shallow roots and lower trunk by fire and decay, coupled with the tremendous weight of the trees, results in the tree falling over. Sometimes wind, heavy snows, undercutting by streams, or water-soaked soils contribute to the toppling. In its natural range this species is now valued primarily for its aesthetic appeal.

Refuse-derived fuels

The concept of refuse-derived fuels (RDFs) is one that has the potential for addressing two of the most troubling environmental problems in the world at the same time: **solid waste** disposal and a source of energy. The term refuse-derived fuel refers to any process or method by which waste materials are converted into a form in which they can be burned as a source of energy.

In regions of the world characterized by a throw-away ethic and swamped with essentially non-degradable materials, accumulation and disposal of solid waste continue to be a growing problem. In 1960, each American generated 2.7 lb (1.2 kg) of solid waste. This grew to 4.3 lb (1.9 kg) per person by 1990. Americans continue to generate more solid waste each day but the rate of growth has decreased. In 2002, every man, woman, and child in the United States produced an average of 4.5 lb (2.0 kg) of waste each day.

Materials are labeled wastes because they tend to have no future use once they are discarded. Yet, by their very

nature, most solid wastes are potentially valuable as fuels. A typical sample of municipal waste in the United States, for instance, may consist of about 30–40% paper, 5% textiles, 5% wood, and 20–30% organic material. All of these materials are combustible. Metals, glass, **plastics**, sand, and other non-combustible materials constitute the remaining portion of a waste sample. Each of these non-combustible materials is potentially recyclable.

Even though 70% or more of municipal wastes appear to have potential value as sources of fuel, that potential has not, as yet, been extensively developed. In most countries, solid wastes are mainly disposed of in landfills. A small fraction is incinerated or used for other purposes. However, conversion of solid wastes to a useable fuel is still an experimental process.

The primary roadblock to the commercial development of RDFs is the economic cost of preparing such fuels. Given that most RDFs produced have only about half the energy value of a typical sample of industrial **coal** and given the relatively low price of coal, there is little economic incentive for municipalities to build energy systems based on refuse-derived fuels.

Many scientists, engineers, and environmentalists see a positive future for refuse-derived fuels. They argue that as fossil fuel reserves are consumed, the cost of traditional fuels such as coal, gas, and oil will inevitably increase. In addition, RDFs tend to burn more cleanly and have a significant environmental advantage over coal and other **fossil fuels**. Research must continue, therefore, to develop more efficient and less expensive RDFs and associated processes to obtain and use them.

One of the fundamental problems in the development of refuse-derived fuels is obtaining the raw materials in a physical condition that will allow the extraction of combustible organic matter. The solid waste material entering most landfills consists of a complex mixture of substances. Some of these are combustible while others are not. Some have other commercial values while others have none. Plastics provide a convenient example that illustrates both of these aspects.

The first step in preparing wastes for the production of refuse-derived fuels is known as size reduction. In this step, waste materials are shredded, chopped, sliced, pulverized, or otherwise treated in order to break them up into smaller pieces. Most methods for separating combustible from non-combustible materials require that waste particles be small in size. Both **magnetic separation** and air classification will work only with small particles.

Size reduction also serves a number of other functions. For example, it breaks open plastic and glass bottles, releasing any contents that may still be in them. It also reduces clumping and tangling that often occurs with larger particles. Finally, when used as a fuel, particles of small size burn more efficiently than larger particles.

One indication of the importance of size reduction in the production of RDFs is the number of different machines that have been developed to accomplish this step. Bag breakers are used to tear open plastic bags and cardboard boxes. Machines called chippers reduce cut wood into small pieces. Granulators have sharp knives on rotating blades. These devices cut materials against a stationary blade, somewhat similar to a pair of scissors. Flail mills are rotary machines that swing hammers around in a circle to smash materials. Ball and rod mills consist of cylindrical drums that hold balls or rods. When the drums spin, balls or rods smash against the inside of the drum, crushing solid wastes also present in them.

Once waste materials have been reduced in size, the portion that is combustible must be removed from that which is not. Several different procedures can be used. A common process, for example, is to pass the solid wastes under a magnet. The magnet will extract all metals containing iron (ferrous) from the mixture.

Another technique is rotary screening, in which wastes are spun in a drum and sorted using screens that have openings of either 50 mm or 200 mm diameter. Sand, broken glass, dust, and other non-organic materials that do not burn tend to be removed by this procedure.

A third process is known as air classification. When solid wastes are exposed to a blast of air, various components are separated from each other on the basis of their size, shape, density, and moisture content. A number of different kinds of air classifiers exist, and all are reasonably efficient in separating organic from inorganic materials.

One type of air classifier is the horizontal model, in which size-reduced wastes are dropped into a horizontal stream of air. Various types of material are separated on the basis of the horizontal distance they travel from their point of origin. Vertical classifiers separate on a similar principle except that particles are injected into a rising stream of air. The rotary classifier consists of an inclined cylindrical column into which wastes are injected and then separated by a rotating, rising column of air.

The organic matter that remains after size reduction and separation can be used as a fuel in four distinct ways. First of all, it can be converted to other combustible forms through pyrolysis. Pyrolysis is a process in which organic materials are heated to high temperatures in an oxygen-free or oxygen-deficient **atmosphere**. The product of this reaction is a mixture of gaseous, liquid, and solid compounds. The solid compounds can be used as fuels and are collectively called char.

Two particularly valuable fuels, **methane** (a gas) and **ethanol** (ethyl alcohol, a liquid), can also be produced from

organic wastes. Scientists have long known that methane is produced when **anaerobic** bacteria act on organic compounds found in solid wastes. They have successfully extracted methane from landfills and used it as a fuel. However, they have achieved only limited success in generating methane from other refuse outside of landfills.

Some success has been obtained in the production of ethanol from wastes. This process separates materials containing cellulose from other wastes and then hydrolyzes them in an acidic medium. As of 2002, ethanol has not been generated in commercially useful amounts from solid waste streams. However, ethanol has been obtained from corn and some other crop materials. In some states, ethanol is added to **gasoline**, producing a fuel that burns more cleanly and efficiently than pure gasoline.

Some heating systems make use of the dried material produced as a result of size reduction and separation directly as a fuel. The Imperial Metal Industries (IMI) company in Birmingham, England, has operated such a plant since 1976. Solid wastes provided by the West Midlands County Council is delivered to the IMI plant where it is reduced in size, separated, dried, and then fed directly into furnaces, where it is burned. A similar plant operated by Commonwealth Edison and run on wastes from the city of Chicago was opened in 1978.

A convenient and popular method of handling RDFs is to process them as pellets or briquettes. Pellets are formed from wastes that have been size reduced, separated, and partially dried. The material is extruded through a dye or compacted into small nuggets in devices known as densifying machines. An important factor in the success of this method is keeping the wastes moist enough to stick together, but dry enough for efficient **combustion**.

Finally, research has been conducted on the use of RDFs in combustion systems, such as **fluidized bed combustion**. In this process, fuel is mixed with some material such as sand and suspended in a furnace by a stream of air. The second material makes thorough mixing of the fuel possible. The fuel is then burned in the air stream.

A considerable number of research and engineering studies have been conducted on refuse-derived fuels. As of 2002, many municipalities operate plants that generate electricity. With the help of modest tax benefits in some but not all areas, most of these facilities are commercially successful. They have reduced the volume of waste entering local landfills. In turn, the life of existing landfills has been extended and the need to open new landfills has been reduced. They generate a modest but significant proportion of electricity for customers in their municipalities.

Tom [Thomas Howard] Regan (1938 –)

American philosopher and animal rights activist

Regan is a well-known figure in the animal liberation movement. His *The Case for Animal Rights* (1983) is a systematic and scholarly defense of the controversial claim that animals have rights that humans are morally obligated to recognize and respect. Arguing against the views of earlier philosophers like René Descartes, who claimed that animals are machine-like and incapable of having mental states such as consciousness or feelings of pleasure or pain, Regan attempts to show that such a view is misguided, muddled, or incorrect.

Regan was born in Pittsburgh, Pennsylvania. He attended Thiel College and the University of Virginia, where he earned his doctorate in philosophy. Before publishing *The Case for Animal Rights*, Regan also edited *Animal Rights and Human Obligations* (1976) and *Matters of Life and Death* (1980).

Within the **animal rights** movement, Regan disagrees with certain philosophical arguments advanced in defense of animal liberation by, most notably, the nineteenth-century English philosopher Jeremy Bentham and the twentieth-century Australian philosopher **Peter Singer**. Both Bentham and Singer are utilitarians who believe that morality requires the pleasures of all sentient creatures—human and nonhuman alike—be maximized and their pain minimized. From a utilitarian perspective, most discussions about rights are unnecessary. Regan disagrees, arguing that sentience—the ability to feel pleasure and pain—is an inadequate basis on which to build a case for animal rights and against such

practices as meat-eating, factory farming, fur **trapping**, and the use of animals in laboratory experiments.

Regan is currently a professor at North Carolina State University where he set up the National Bioethics Institute in 1999. He was also the recipient of the 2000 Holladay Medal. Regan views the case for animal rights as an integral part of a broader and more inclusive environmental ethic. He predicts and participates in the coming of a new kind of revolution—a revolution of gentility and concern—made not by a self-centered *me-generation* but by an emerging *thee generation* of caring and concerned people from every political party, religion, and socioeconomic class. Among the indications of this forthcoming revolution is the growing popularity of and financial support for the various groups and organizations that comprise the more broadly based environmental and animal rights movements.

Regulatory review

The regulatory review process allows the executive branch of the United States federal government to ensure that the regulations drafted by different agencies contribute to the current administration's overall goals. Regulatory review is also carried on at the state level, although the organizational structure of these councils or commissions varies somewhat from state to state. In the past the regulatory review process has emphasized a **cost-benefit analysis** that has tended to delay or halt the publication of environmental regulations. This pattern shifted after 1993 to a greater emphasis on citizen participation in the process of rulemaking.

Executive agencies carry out congressionally enacted laws by drafting and enforcing regulations. The **Environmental Protection Agency** (EPA) has responsibility for writing the regulations that implement environmental laws, like the **Clean Air Act** and the Comprehensive Environmental Response, Compensation and Liability Act (Superfund). For example, when the **Resource Conservation and Recovery Act** (RCRA) called for states to protect **groundwater** from **landfill** leachate, the EPA drafted a regulation that included specifications for the kind of equipment that landfills should install to ensure that leachate would not leak.

An emerging concern in regulatory review is the spiraling costs of regulations related to the **environment**. The price tag on environmental regulation has tripled over the last quarter century, from about $80 billion in 1977 to more than $267 billion in 2000. In addition, a recent study of regulatory review found that federal agencies involved with environmental regulations received the largest increases in the federal budget in recent years, the EPA in particular receiving an increase of over $1 billion for the fiscal year 2002.

Once drafted, before being published for public comment, all regulations are sent for review to the Office of Information and Regulatory Affairs (OIRA) within the **Office of Management and Budget** (OMB). OIRA either approves, rejects, or asks for specific changes in the regulation. If a regulation is approved it can be published on the Internet or in hard copy for public comment.

This centralization of the regulatory process was accomplished by Ronald Reagan's executive orders 12291 and 12498. Executive Order 12291, issued in 1981, established a cost-benefit review process. All federal agencies must weigh costs and benefits for each "major" regulation and submit these considerations to OIRA. (A "major" regulation costs more than $100 million or is otherwise deemed major by OIRA.) Agencies cannot publish proposed or final rules until OIRA has ensured that the benefits of a regulation outweigh the costs. Executive Order 12498, issued in 1984, requires agency heads to predict their regulatory actions for the following year. All regulations are then compiled into the *Regulatory Program*. Compiling this program allows OIRA to be involved in the early planning stages of all regulations.

In September 1993, Executive Orders 12291 and 12498 were replaced by President Clinton with Executive Order 12866 on regulatory planning and review. While Executive Order 12866 left the basic structure of OIRA in place, including the figure of $100 million as the standard of a major regulation, the order was intended to harmonize federal regulations regarding the environment with related state, local, and tribal regulations and procedures. The order also allowed for negotiated rulemaking and other consensual approaches to developing regulations in appropriate situations. A third important feature of Executive Order 12866 is its emphasis on transparency; that is, federal agencies are not only required to "provide the public with meaningful participation in the regulatory process," but also to allow time for comments on proposed regulations. To facilitate citizens' participation and response, all regulatory information is to be provided to the public "in plain, understandable language."

Executive Order 12866 became the basis for the establishment of two online databases maintained by OMB for purposes of regulatory review and communication with the public. OIRA has a Regulation Tracking System, or REGS, to monitor the regulatory review process. When a proposed regulation is submitted to OIRA, the REGS system verifies the information contained in the document and assigns each submission a unique OMB tracking number. It then prints out a worksheet for review. After the worksheet has been reviewed, its contents are entered into the REGS system and maintained in its database. REGS also provides a listing, updated daily, of all pending and recently approved regulations on the OMB home page. The OIRA Docket Library maintains certain records related to proposed Federal regulatory actions reviewed by OIRA under Executive Order 12866. Telephone logs and materials from public meetings attended by the OIRA Administrator are also available in the Docket Library. A major upgrading of OIRAs information system is scheduled for the second half of 2002.

Though administrations and policy priorities change, the regulatory review process will most likely remain centralized in the Office of Information and Regulatory Affairs. This office allows the president to ensure that agencies implement legislation through regulations that reflect the central priorities of the administration. For example, Executive Order 13211, signed by President George W. Bush on May 22, 2001, requires federal agencies to submit a formal Statement of Energy Effects to OIRA along with their submissions of proposed regulations. The Statement of Energy Effects must include a description of any negative effects on the supply, distribution, or use of energy that are likely to result from a proposed regulation. These negative effects could include lowered production of **coal**, oil, gas, or electricity; increased costs; or harm to the environment. The order does not, however, change the basic process of regulatory review.

One structural modification that may be made within the next few years, however, is related to the computerization of government information. As of 2002, the federal government does not have a "seamless" system of data collection, analysis, and use. For the past several decades, government agencies have purchased computers and software systems on their own, without any attempt to coordinate their systems with those of other agencies. The lack of a unified computer language complicates the process of regulatory review as well as contributing to overall inefficiency and higher costs. In the summer of 2002, the Senate passed a bill called the E-Government Act, intended to help government agencies communicate more effectively with one another as well as make government information more accessible to citizens. The E-Government Act would allocate $345 million over a four-year period to help federal agencies upgrade their online services, and to establish an Office of Electronic Government alongside OIRA under the Office of Management and Budget.

Rehabilitation

Rehabilitation is a process which is being applied more frequently to the **environment**. It aims to reverse the deterioration of a national resource, even if it cannot be restored to its original state.

Attempts to rehabilitate deteriorated areas have a long history. In England, for example, gardener and architect Lancelot "Capability" Brown devoted his life to restoring vast stretches of the English countryside that had been dramatically modified by human activities.

Reforestation was one of the common forms of rehabilitation used by Brown, and this method continues to be used throughout the world. The demand for wood both as a building material and a source of fuel has resulted in the devastation of forests on every continent. Sometimes the objective of reforestation is to ensure a new supply of lumber for human needs, and in other cases the motivation is to protect the environment by reducing land **erosion**. Aesthetic concerns have also been the basis for reforestation programs. Recently, the role of trees in managing atmospheric **carbon dioxide** and global climate has created yet another motivation for the planting of trees.

Another activity in which rehabilitation has become important is **surface mining**. The process by which **coal** and other minerals are mined using this method results in massive disruption of the environment. For decades, the policy of mining companies was to abandon damaged land after all minerals had been removed. Increasing environmental awareness in the 1960s and 1970s led to a change in that policy, however. In 1977, the United States Congress passed the **Surface Mining Control and Reclamation Act** (SMCRA), requiring companies to rehabilitate land damaged by these activities. The act worked well at first and mining companies began to take a more serious view of their responsibilities for restoring the land they had damaged, but by the mid-1980s that trend had been reversed to some extent. The Reagan and Bush administrations were both committed to reducing the regulatory pressure on American businesses, and tended to be less aggressive about the enforcement of environmental laws such as SMCRA.

Rehabilitation is also widely used in the area of human resources. For example, the spread of urban blight in American cities has led to an interest in the rehabilitation of public and private buildings. After World War II, many people moved out of central cities into the suburbs. Untold numbers of houses were abandoned and fell into disrepair. In the last decade, municipal, state, and federal governments have shown an interest in rehabilitating such dwellings and the areas where they are located. Many cities now have urban homesteading laws under which buildings in depressed areas are sold at low prices, and often with tax breaks, to buyers who agree to rehabilitate and live in them. *See also* Environmental degradation; Environmental engineering; Forest management; Greenhouse effect; Strip mining; Restoration ecology; Wildlife rehabilitation

William Kane Reilly (1940 –)

American conservationist and Environmental Protection Agency administrator

Called the "first professional environmentalist" to head the **Environmental Protection Agency** since its founding in 1970, Reilly came to the agency in 1989 with a background in law and urban planning. He had been appointed to President Richard Nixon's **Council on Environmental Quality** in 1970, and was named executive director of the Task Force on **Land Use** and Urban Growth two years later. In 1973, Reilly became president of the Conservation Foundation, a non-profit environmental research group based in Washington, D.C., which he is credited with transforming into a considerable force for environmental protection around the world. In 1985, the Conservation Foundation merged with the **World Wildlife Fund**; Reilly was named as president, and under his direction, membership grew to 600,000 with an annual budget of $35 million.

William K. Reilly describing the Bush administration's clean air proposals in 1989. (Corbis-Bettmann. Reproduced by permission.)

Reilly began to cautiously criticize White House **environmental policy** during Ronald Reagan's administration, objecting to the appointments of **James G. Watt**, and his successor William P. Clark, as secretary of the interior. He published articles and spoke publicly about **pollution**, **species** diversification, **rain forest** destruction, and **wetlands** loss.

After his confirmation as EPA administrator, Reilly laid out an agenda that was clearly different from his predecessor, Lee Thomas. Reilly promised "vigorous and aggressive enforcement of the environmental laws," a tough new **Clean Air Act**, and an international agreement to reduce **chlorofluorocarbons** (CFCs) in the **atmosphere**. Calling toxic waste cleanup a top priority, Reilly also promised action

to decrease urban **smog**, remove dangerous **chemicals** from the market more quickly, encourage strict fuel efficiency standards, increase **recycling** efforts, protect wetlands, and encourage international cooperation on global warming and **ozone layer depletion**.

In March 1989, Reilly overruled a recommendation of a regional EPA director and suspended plans to build the Two Forks Dam on the South Platte River in Colorado. The decision relieved environmentalists who had feared construction of the dam would foul a prime trout stream, flood a scenic canyon, and disrupt **wildlife migration** patterns. That same year, Reilly criticized the federal government's response to the grounding of the ***Exxon Valdez*** and the oil spill in **Prince William Sound**, Alaska.

At Reilly's urging, President George Bush proposed major revisions of the Clean Air Act of 1970. The new act required public utilities to reduce emissions of **sulfur dioxide** by nearly half. It also contained measures that reduced emissions of toxic chemicals by industry and lowered the levels of urban smog.

Under Reilly's direction, the EPA also enacted a gradual ban on the production and importation of most products made of **asbestos**. He left the agency in 1992, and in 1993 became President and Chief Executive Officer of Aqua International Partners, L. P.

Relict species

A **species** surviving from an ancient time in isolated populations that represent the localized remains of a distribution which was originally much wider. These populations become isolated through disruptive geophysical events such as **glaciation**, or immigration to outlying islands, which is not followed by reunification of the fragmented populations. The origins and relationships of several relict species are well documented, and these include local Central American avian populations which are remnants of the North American avifauna left after the last glacial retreat. The origins of other relict species are unknown because all related species are extinct. This group includes lungfishes, rhynchocephalian reptiles (genus *Sphenodon*), and the duck-billed platypus (*Ornithorhynchus anatinus*). *See also* California condor; Endangered species; Extinction; Rare Species

Religion and the environment

All of the world's major faiths have, as integral parts of their laws and traditions, teachings requiring protection of the **environment**, respect for **nature** and **wildlife**, and kindness to animals. While such tenets are well-known in such Eastern religions as Buddhism and Hinduism, there is also a largely-forgotten but strong tradition of such teachings in Christianity, Judaism, and Islam. All of these faiths recognize a doctrine of their deity's love for creation and for all of the living creatures of the world. The obligation of humans to respect and protect the natural environment and other life forms appears throughout the sacred writings of the prophets and leaders of the world's great religions.

These tenets of "environmental theology" contained in the world's religions are infrequently observed or practiced, but many theologians feel that they are more relevant today than ever. At a time when the earth faces a potentially fatal ecological crisis, these leaders say, traditional religion shows us a way to preserve our planet and the interdependent life forms living on it. Efforts are under way by representatives of virtually all the major faiths to make people more aware of the strong **conservation** and humane teachings that are an integral part of the religions of most cultures around the globe. This movement holds tremendous potential to stimulate a spiritually-based ecological ethic throughout the world to improve and protect the natural environment and the welfare of humans who rely upon it.

The Bible's ecological message

The early founders and followers of monotheism were filled with a sense of wonder, delight, and awe of the greatness of God's creation. Indeed, nature and wildlife were sources of inspiration for many of the prophets of the Bible. The Bible contains a strong message of conservation, respect for nature, and kindness to animals. It promotes a reverence for life, for "God's Creation," over which humans were given stewardship responsibilities to care for and protect. The Bible clearly teaches that in despoiling nature, the Lord's handiwork is being destroyed and the sacred trust as caretakers of the land over which humans were given stewardship is violated.

Modern-day policies and programs that despoil the land, desecrate the environment, and destroy entire **species** of wildlife are not justified by the Bible. Such actions clearly violate biblical commands to humans to "replenish the earth," conserve **natural resources**, and treat animals with kindness, and to animals to "be fruitful and multiply" and fill the earth. For example, various laws requiring the protection

of natural resources are found in the Mosaic law, including passages mandating the preservation of fruit trees (Deuteronomy 20:19, Genesis 19:23–25); agricultural lands (Leviticus 25:2–4); and wildlife (Deuteronomy 22:6–7; Genesis 9). Numerous other biblical passages extol the wonders of nature (Psalms 19, 24, and 104) and teach kindness to animals, including the Ten Commandments, which require that farm animals be allowed to rest on the Sabbath.

Christianity: Jesus' nature teachings

The New Testament contains many references by Jesus and his disciples that teach people to protect nature and its life forms. Throughout the Sermon on the Mount, Jesus used nature and pastoral imagery to illustrate his points and uphold the creatures of nature as worthy of being emulated. In stressing the lack of importance of material possessions such as fancy clothes, Jesus observed that "God so clothes the grass of the field" and cited wildflowers as possessing more beauty than any human garments ever could: "Consider the lilies of the field, how they grow; they toil not, neither do they spin. And yet I say unto you, that even Solomon in all his glory was not arrayed like one of these" (Matthew 6:28–30; Luke 12:27). In Luke 12:6 and Matthew 10:29, Jesus stresses that even the lowliest of creatures is loved by God: "Are not five sparrows sold for two pennies? And not one of them is forgotten before God."

Judaism: a tradition of reverence for nature

The teachings and laws of Judaism, going back thousands of years, strongly emphasize kindness to animals and respect for nature. Indeed, an entire code of laws relates to preventing "the suffering of living creatures." Also important are the concepts of protecting the elements of nature, and *tikkun olam*, or "repairing the world." Jewish prayers, traditions, and literature contain countless stories and admonitions stressing the importance of the natural world and animals as manifestations of God's greatness and love for His creation.
